A **bicomplex** (or **double complex**) C in \mathcal{C} consists of objects $C^{p,q}$ ($p, q \in \mathbf{Z}$) and two differentials $d_1: C^{p,q} \rightarrow C^{p+1,q}$, $d_2: C^{p,q} \rightarrow C^{p,q+1}$ subject to $d_1^2 = d_2^2 = 0$ and $d_1 d_2 = d_2 d_1$ (sometimes replaced by anticommutativity, $d_1 d_2 + d_2 d_1 = 0$). Morphisms of bicomplexes are defined as for single complexes. A bicomplex C becomes a (single) complex if we put $C^n = \sum_{p+q=n} C^{p,q}$ (when the sum exists) and define the differential d to be $d_1 + (-1)^p d_2$ on $C^{p,q}$. Then d is called the **total differential** and d_1, d_2 the **partial differentials**. On the other hand, $C_1^q = \{C^{p,q} (p \in \mathbf{Z}), d_1\}$ constitutes a complex for each q , whose cohomology $H^p(C_1^q)$ is denoted by $H_1^p(C^q)$. Then d_2 induces morphisms $H_1^p(C^q) \rightarrow H_1^p(C^{q+1})$, so that we obtain a complex $H_1^p(C)$. The cohomology of $H_1^p(C)$ is denoted by $H_2^q(H_1^p(C))$. We define $H_1^p(H_2^q(C))$ similarly. The cohomology of C with respect to the total differential is denoted simply by $H^n(C)$. Similar constructions are applied to double chain

complexes $\{C_{p,q}\}$ and further to **multiple complexes**, as we shall show in the case of bicomplexes.

Let T be a \dagger bifunctor $\mathcal{C}_1 \times \mathcal{C}_2 \rightarrow \mathcal{C}'$ and C_i be complexes in \mathcal{C}_i ($i = 1, 2$). Then $T(C_1, C_2)$ is a bicomplex in \mathcal{C}' . For instance, $\text{Hom}(C', C)$ is a positive (bipositive) complex if $C(C')$ is a positive (negative) complex in \mathcal{C} . If C, C' are complexes in $\mathcal{M}_R, {}_R\mathcal{M}$, respectively, the \dagger tensor product $C \otimes_R C'$ is a complex in (Ab) (the **product complex**). There is a canonical morphism $H_p(C) \otimes H_q(C') \rightarrow H_{p+q}(C \otimes C')$. If C_n and B_n are \dagger flat for all $n \in \mathbf{Z}$, we have the following exact sequence (**Künneth's formula**):

$$0 \rightarrow \sum_{p+q=n} H_p(C) \otimes H_q(C') \rightarrow H_n(C \otimes C') \\ \rightarrow \sum_{p+q=n-1} \text{Tor}_1(H_p(C), H_q(C')) \rightarrow 0$$

(for the definition of Tor → Section D). For $C' = A \in {}_R\mathcal{M}$, Künneth's formula reduces to the exact sequence $0 \rightarrow H_n(C) \otimes A \rightarrow H_n(C \otimes A) \rightarrow \text{Tor}_1(H_{n-1}(C), A) \rightarrow 0$ (**universal coefficient theorem**). The corresponding exact sequence for cohomology is

$$0 \rightarrow \text{Ext}^1(H_{n-1}(C), A) \rightarrow H^n(C, A) \\ \rightarrow \text{Hom}(H_n(C), A) \rightarrow 0$$

(→ Section G; 201 Homology Theory).

I. Satellites and Derived Functors

Let \mathcal{C} and \mathcal{C}' be Abelian categories. All functors in this section are \dagger additive. A \dagger covariant functor $T: \mathcal{C} \rightarrow \mathcal{C}'$ is called **exact** if T maps every exact sequence in \mathcal{C} to an exact sequence in \mathcal{C}' . T is called **half-exact**, **left exact**, or **right exact** if for every **short exact sequence** $0 \rightarrow A \rightarrow B \rightarrow C \rightarrow 0$, the sequence $T(A) \rightarrow T(B) \rightarrow T(C)$, $0 \rightarrow T(A) \rightarrow T(B) \rightarrow T(C)$, or $T(A) \rightarrow T(B) \rightarrow T(C) \rightarrow 0$, respectively, is exact. Similar definitions apply for \dagger contravariant functors. The functor $\text{Hom}: \mathcal{C} \times \mathcal{C} \rightarrow (\text{Ab})$ (which defines the category \mathcal{C}) is left exact in both factors. An object P is **projective** if $h_p(\cdot) = \text{Hom}(P, \cdot)$ is exact, while Q is **injective** if $h^q(\cdot) = \text{Hom}(\cdot, Q)$ is exact. If every object A admits a \dagger epimorphism from a projective object $P \rightarrow A$ (resp. \dagger monomorphism into an injective object $A \rightarrow Q$), \mathcal{C} is said to have enough projectives (injectives). An object G is called a **generator (cogenerator)** if the natural mapping $\text{Hom}(A, B) \rightarrow \text{Hom}(h_G(A), h_G(B))$ ($\text{Hom}(h^G(B), h^G(A))$) is one-to-one.

An Abelian category \mathcal{C} is called a **Grothendieck category** if (1) \mathcal{C} has a generator, (2) \dagger direct sums always exist, and (3) the identity $(\bigcup A_i) \cap B = \bigcup (A_i \cap B)$ holds for any object A , its \dagger subobject B , and a \dagger totally ordered family $\{A_i\}$ of subobjects. A Grothendieck cate-

gory has enough injectives (R. Baer, 1940, for (Ab); A. Grothendieck, 1957, for general \mathcal{C}). A monomorphism into an injective object $f: A \rightarrow Q$ is called an **injective envelope** if $\text{Im } f \cap \text{Im } g \neq 0$ for any nonzero monomorphism $g: B \rightarrow Q$. Every object A in a Grothendieck category admits an injective envelope, which is unique up to isomorphism (B. Eckmann and A. Schopf, 1953, for ${}_R\mathcal{M}$; B. Mitchell, 1960, for general \mathcal{C}).

We say that a covariant ∂ -**functor** $\mathcal{C} \rightarrow \mathcal{C}'$ is given if we have a sequence of covariant functors $T = \{T^i: \mathcal{C} \rightarrow \mathcal{C}'\}$ and the **connecting morphisms** $\partial: T^i(A') \rightarrow T^{i+1}(A')$ for an arbitrary short exact sequence $0 \rightarrow A' \rightarrow A \rightarrow A'' \rightarrow 0$ satisfying the following conditions: (i) $\partial \circ T^i(f'') = T^{i+1}(f') \circ \partial$ for a morphism f of short exact sequences; and (ii) the sequence $\dots \rightarrow T^{i-1}(A') \xrightarrow{\partial} T^i(A') \rightarrow T^i(A) \rightarrow T^i(A'') \xrightarrow{\partial} T^{i+1}(A') \rightarrow \dots$ constitutes a complex. $T = \{T^i\}$ is called a covariant ∂^* -**functor** if instead of ∂ there are given $\partial^*: T^i(A'') \rightarrow T^{i-1}(A')$ satisfying similar conditions (i*) and (ii*). By taking duals, we define the notion of contravariant ∂ - and ∂^* -functors. They are also called **connected sequences of functors**. A ∂ -(∂^*)-functor defined for $-\infty < i < +\infty$ is called a **cohomological functor (homological functor)** if the sequence in condition (ii) (resp. (ii*)) is always exact. A morphism of ∂ -functors $f: S \rightarrow T$ consists of natural transformations $f^i: S^i \rightarrow T^i$ that commute with the connecting morphisms. A ∂ -functor S defined for $a \leq i < b$ is called **universal** if for any ∂ -functor T defined in the same interval and any natural transformation $\varphi: S^a \rightarrow T^a$, there exists one and only one morphism $f: S \rightarrow T$ such that $f^a = \varphi$. Let $F: \mathcal{C} \rightarrow \mathcal{C}'$ be a covariant functor and b any positive integer. A universal covariant ∂ -functor S defined for $0 \leq i < b$ is called a **right satellite** of F if $S^0 = F$ (S is then denoted by $\{S^i F\}$). If such an S exists, then it is unique and satisfies $S^{i+1}(F) = S^1(S^i F)$. If \mathcal{C} has enough injective objects, the right satellites always exist, and if F is left exact, then $\{S^i F\}$ is a cohomological functor. The universality of ∂^* -functors is defined by reversing the arrows; the satellites $\{S_i F\}$ are then written as $\{S^{-i} F\}$ and called the **left satellites**.

Let \mathcal{C} be an Abelian category with enough injectives. An **injective resolution** of an object A is a right resolution $Q = \{Q^i\}$ such that all Q^i are injective. Every A admits an injective resolution, which is unique up to chain equivalence (H. Cartan, 1950). For a covariant functor $F: \mathcal{C} \rightarrow \mathcal{C}'$, the functor $A \rightarrow H^i(F(Q))$, called the i th **right derived functor** $R^i F$ of F , is independent of Q . $\{R^i F\}$ is a cohomological functor. By the universality of satellites, there exists a morphism of ∂ -functors $\{S^i F\} \rightarrow \{R^i F\}$ which is an isomorphism if and only if F is left exact. The

left derived functors $L_i F$ of a contravariant functor F are defined similarly and are isomorphic to the left satellites when F is right exact. If \mathcal{C} has enough projectives (instead of injectives), we define left (right) derived functors of covariant (contravariant) functors via **projective resolutions**. For a multifunctor, we define **partial derived functors** as well as (total) derived functors of the functor viewed as a functor defined in the \dagger product category. For instance, let $T(A, B): \mathcal{C}_1 \times \mathcal{C}_2 \rightarrow \mathcal{C}'$ be contravariant in A and covariant in B . When \mathcal{C}_2 has enough injectives, we obtain $R_2^i T(A, B) = H^i(T(A, Q))$ using an injective resolution Q of B . Suppose that T satisfies condition (i) $A \rightarrow T(A, B)$ is exact for any injective B . Then for a fixed injective B , $R_2^i T(A, B)$ is a cohomological functor in A . When A has a projective resolution P in \mathcal{C}_1 , we obtain $R_1^i T(A, B) = H^i(T(P, B))$ as well as the equation for the total derived functor $R^i T(A, B) = H^i(T(P, Q))$. We say that a functor T is **right balanced** if it satisfies (i) and also (ii) $B \rightarrow T(A, B)$ is exact for any projective A . In this case, the three derived functors are isomorphic. The **left balanced** functors are defined similarly. When the right derived functors of the functor Hom (which defines the category) exist, they are denoted by $\text{Ext}^i(A, B)$.

J. Spectral Sequences

In this section, we deal with cohomology in the category ${}_R\mathcal{M}$ of R -modules. A similar theory for homology is obtained by modifying the theory in a natural way. Similar constructions are also possible for general Abelian categories [3, 8].

A **filtration** F of a module A is a family of submodules $\{F^p(A) | p \in \mathbb{Z}\}$ such that $F^p(A) \supset F^{p+1}(A)$. We say that the filtration F is **convergent from above** (or **exhaustive**) if $\bigcup_p F^p(A) = A$, and F is **bounded from below** (or **discrete**) if $F^p(A) = 0$ for some p . The \dagger graded module $G(A) = \{G^p(A) = F^p(A)/F^{p+1}(A) | p \in \mathbb{Z}\}$ is said to be **associated** with A . A **morphism** of filtered modules $f: A \rightarrow A'$ is a module homomorphism such that $f(F^p(A)) \subset F^p(A')$. It induces a homomorphism of the graded modules $G(A) \rightarrow G(A')$. A filtration of a complex $C = \{C^n, d\}$ consists of subcomplexes $F^p(C) = \{F^p(C^n)\}$ such that $F^p(C) \supset F^{p+1}(C)$. We assume that the complex C satisfies $\bigcup_p F^p(C) = C$, and is bounded from below; i.e., for every n there exists some p such that $F^p(C^n) = 0$. In particular, if $F^0(C) = C$, $F^{p+1}(C^p) = 0$, the complex C is called **canonically bounded**. Writing $C^{p,q} = G^p(C^{p+q})$, we obtain a \dagger bigraded module $\{C^{p,q}\}$, in which p , q , and $p+q$ are called the

filtration degree, the **complementary degree**, and the **total degree**, respectively.

A **spectral sequence** $\{E_r\}$ with a graded module $D = \{D^n\}$ as its **limit** (denoted by $E_2^{p,q} \Rightarrow_p D^n$) consists of a family of doubly graded modules $E_r = \{E_r^{p,q} \mid p, q \in \mathbb{Z}\}$ ($r \geq 2$ or sometimes $r \geq 1$) and differentiations $d_r: E_r^{p,q} \rightarrow E_r^{p+r, q-r+1}$ ($p, q \in \mathbb{Z}$) of degree $(r, 1-r)$ satisfying $d_r^2 = 0$ and satisfying the following two conditions: (i) $H(E_r)$ (with respect to d_r) is isomorphic to E_{r+1} (hence there exists a sequence of graded submodules of $E_2: 0 = B_2 \subset B_3 \subset \dots \subset Z_3 \subset Z_2 = E_2$ such that $Z_r/B_r \cong E_r$); and (ii) there are submodules Z_∞ and B_∞ such that $\bigcup_k B_k \subset B_\infty \subset Z_\infty \subset \bigcap_k Z_k$, and $E_\infty = Z_\infty/B_\infty$ is isomorphic to the doubly graded module associated with a certain filtration F of D (i.e., $E_\infty^{p,q} \cong G^p(D^{p+q})$). We assume that $Z_\infty = \bigcap_k Z_k$ and $B_\infty = \bigcup_k B_k$ (**weak convergence**). Suppose that F is convergent from above and bounded from below and that $Z_k(E_2^{p,q})$ is stationary for every p, q . Then $\{E_r\}$ is called **regular**. $\{E_r\}$ is **bounded from below** if for every n there exists a p_0 such that $E_2^{p,q} = 0$ for $p < p_0$. In particular, if $E_2^{p,q} = 0$ ($p < 0, q < 0$), then $\{E_r\}$ is called the **first quadrant** (or **cohomology spectral sequence**). In the latter case, the **edge homomorphisms** $E_2^{p,0} \rightarrow E_\infty^{p,0}$, $E_\infty^{0,q} \rightarrow E_2^{0,q}$ are defined through **base terms** $E_k^{p,0}$ and **fiber terms** $E_k^{0,q}$, respectively. A morphism of spectral sequences $f: \{E_r, D\} \rightarrow \{E'_r, D'\}$ consists of $f_r: E_r \rightarrow E'_r$ of degree $(0, 0)$ and $f: D \rightarrow D'$ of degree 0 which preserve the mechanism of spectral sequences. When the spectral sequences are regular, a morphism f is an isomorphism if one of the f_r is an isomorphism. Addition is naturally introduced in the set of morphisms so that spectral sequences form an additive category. An additive functor from an Abelian category \mathcal{C} to this category is called a **spectral functor**. A filtered complex $\{C, F\}$ gives rise to a spectral sequence $E_2^{p,q} \Rightarrow G(H(C))$ if we put $Z_r^p = \{a \in F^p(C) \mid da \in F^{p+r}(C)\}$, $B_r^p = dZ_r^{p-r}$, $E_r^p = Z_r^p/(Z_{r-1}^{p+1} + B_{r-1}^p)$, $E_r = \sum_p E_r^p$. A double complex $C = \{C^{p,q}, d_I, d_{II}\}$ admits two natural filtrations $F_I: F_I^p(C) = \sum_{s \geq p} \sum_q C^{s,q}$ and $F_{II}: F_{II}^q(C) = \sum_{t \geq q} \sum_p C^{p,t}$. By the procedure above, these filtrations give rise to spectral sequences $H_I^p(H_{II}^q(C)) \Rightarrow_p H^n(C)$ and $H_{II}^q(H_I^p(C)) \Rightarrow_q H^n(C)$, respectively. Comparison of these sequences yields many useful results. Let T be an additive covariant functor from an Abelian category \mathcal{C} to ${}_R\mathcal{M}$, C be a complex in \mathcal{C} , and $Q = \{Q^{p,q}\}$ be an injective resolution of C . The double complex Q gives rise to spectral sequences $H^p(R^q T(C)) \Rightarrow H(T(Q))$ and $R^p T(H^q(C)) \Rightarrow H(T(Q))$. The limit $H(T(Q))$ is independent of Q and is called the **hypercohomology** of T with respect to C [2, 8]. We can similarly define hypercohomology of multifunctors. The theory of

spectral sequences was initiated by J. Leray (1946), and suitable algebraic formulations were given by J. L. Koszul (1950).

K. Categories of Modules

The category ${}_R\mathcal{M}$ (resp. \mathcal{M}_R) of left (right) R -modules over a \dagger unitary ring R is not only an Abelian category but also a Grothendieck category (\rightarrow 277 Modules). The \dagger full embedding theorem permits us to deduce many propositions about general Abelian categories from the consideration of ${}_R\mathcal{M}$. An object P of ${}_R\mathcal{M}$ is projective if and only if it is isomorphic to a direct summand of a \dagger free module. Any projective module is the direct sum of countably generated projective modules (I. Kaplansky, 1958). It follows that any projective module over a \dagger local ring is free. Finitely generated projective modules P_1 and P_2 are said to be equivalent if there exist finitely generated free modules F_1, F_2 such that $P_1 \oplus F_1 \cong P_2 \oplus F_2$. The equivalence classes then form an Abelian group with respect to the direct sum construction called the **projective class group** of a ring R . The category of complex \dagger vector bundles over a compact space X is equivalent to the category of projective modules over $C(X)$, the ring of complex-valued continuous functions on X , and similarly for other types of spaces and bundles. Many investigations have been made involving the problem of whether every projective module over a polynomial ring is free (J.-P. Serre, 1955). This problem was settled affirmatively by D. Quillen [13] and independently by A. Suslin. It has been observed that "big" projective modules are often free: for example, nonfinitely generated projective modules over an \dagger indecomposable weakly Noetherian ring are free (Y. Hinohara, 1963).

The n th right derived functor of $\text{Hom}_R(A, B)$ is denoted by $\text{Ext}_R^n(A, B)$ (\rightarrow Section G). This is a bifunctor ${}_R\mathcal{M} \times {}_R\mathcal{M} \rightarrow (\text{Ab})$, contravariant in A and covariant in B . Ext_R^0 is isomorphic to and identified with Hom_R . An exact sequence $0 \rightarrow A' \rightarrow A \rightarrow A'' \rightarrow 0$ gives rise to the connecting homomorphisms $\Delta^n: \text{Ext}_R^n(A', B) \rightarrow \text{Ext}_R^{n+1}(A'', B)$, and the following sequence is exact: $\dots \rightarrow \text{Ext}_R^{n-1}(A', B) \xrightarrow{\Delta} \text{Ext}_R^n(A', B) \rightarrow \text{Ext}_R^n(A, B) \rightarrow \text{Ext}_R^n(A'', B) \xrightarrow{\Delta} \text{Ext}_R^{n+1}(A'', B) \rightarrow \dots$ (the exact sequence of Ext). Similarly, an exact sequence $0 \rightarrow B' \rightarrow B \rightarrow B'' \rightarrow 0$ gives rise to $\Delta^n: \text{Ext}_R^n(A, B') \rightarrow \text{Ext}_R^{n+1}(A, B'')$ and to an exact sequence of Ext . An **extension** of A by B (or of B by A) is an exact sequence $(E): 0 \rightarrow B \rightarrow X \rightarrow A \rightarrow 0$. The set of equivalence classes of extensions of A by B is in one-to-one correspondence with $\text{Ext}_R^1(A, B)$ by assigning to (E) its **characteristic class** $\chi_E = \Delta^0(1) \in \text{Ext}_R^1(A, B)$,

where 1 denotes the identity of $\text{Hom}_R(B, B)$. In this correspondence, the sum of two extensions is obtained by a construction called **Baer's sum** of extensions. Similarly, $\text{Ext}_R^n(A, B)$ is interpreted as the set of the equivalence classes of n -fold extensions $0 \rightarrow B \rightarrow X_{n-1} \rightarrow \dots \rightarrow X_0 \rightarrow A \rightarrow 0$ (exact). This point of view permits us to establish a theory of Ext , etc., in more general (additive) categories lacking enough projectives or injectives (N. Yoneda, 1954, 1960).

The tensor product $A \otimes_R B$ is a right exact covariant bifunctor $\mathcal{M}_R \otimes_R \mathcal{M} \rightarrow (\text{Ab})$. If the functor $t_P(\cdot) = \cdot \otimes P$ is exact, P is called a \dagger flat module. A projective module is flat. In general, a flat module is the \dagger inductive limit of finitely generated free modules (M. Lazard, 1964). A flat module P is called \dagger faithfully flat if $P \neq \mathfrak{m}P$ for every maximal ideal \mathfrak{m} of R . The functors \otimes and Hom are related by \dagger adjointness (\rightarrow 52 Categories and Functors). From this viewpoint \otimes can be introduced in more general categories. Left-derived functors of $A \otimes_R B$ are denoted by $\text{Tor}_n^R(A, B)$ and are called n th **torsion products** of A and B . $\text{Tor}_1^R(A, B)$ is often denoted by $A * _R B$. The functor \otimes_R is left balanced, hence Tor is calculated by using projective resolutions of A , B , or both A and B . We have $\text{Tor}_0^R = \otimes_R$. An exact sequence $0 \rightarrow A' \rightarrow A \rightarrow A'' \rightarrow 0$ gives rise to $\Delta_n: \text{Tor}_{n+1}^R(A'', B) \rightarrow \text{Tor}_n^R(A', B)$ and the infinite exact sequence of Tor , and similarly for the second variables.

From the various relations between Hom and \otimes follow the corresponding relations between their derived functors. When Λ and Γ are algebras over K and $\Omega = \Lambda \otimes \Gamma$, we can define the **external product** (\top -**product**), which is a mapping

$$\begin{aligned} \top: \text{Tor}_p^\Lambda(A, B) \otimes \text{Tor}_q^\Gamma(A', B') \\ \rightarrow \text{Tor}_{p+q}^\Omega(A \otimes A', B \otimes B'). \end{aligned}$$

In particular, if Λ and Γ are K -projective and $\text{Tor}_n^K(A, A') = 0$ ($n > 0$), then we can define the **wedge product** (\vee -**product**) $\vee: \text{Ext}_\Lambda^n(A, B) \otimes \text{Ext}_\Gamma^q(A', B') \rightarrow \text{Ext}_\Omega^{n+q}(A \otimes A', B \otimes B')$. The latter is described in terms of the composition of module extensions. When $K = \Lambda = \Gamma = \Omega$, the \top -product reduces to the **internal product**, called the \mathfrak{m} -**product**. If Λ is a \dagger Hopf algebra over K , the \dagger comultiplication $\Lambda \rightarrow \Lambda \otimes \Lambda$ induces $\text{Ext}_{\Lambda \otimes \Lambda} \rightarrow \text{Ext}_\Lambda$. This, combined with the \vee -product, yields the **cup product** (\smile -**product**) $\smile: \text{Ext}_\Lambda^n(A, B) \otimes \text{Ext}_\Lambda^q(A', B') \rightarrow \text{Ext}_\Lambda^{n+q}(A \otimes A', B \otimes B')$. We define similarly \perp -**product**, \wedge -**product**, ω -**product**, and \frown -**product** (**cap product**) [2]. Let Λ , Γ , and Σ be algebras over K , with Λ K -projective; let $A \in \mathcal{M}_{\Lambda \otimes \Gamma}$, $B \in \mathcal{M}_{\Lambda \otimes \Sigma}$, $C \in \mathcal{M}_{\Gamma \otimes \Sigma}$, and assume $\text{Tor}_n^\Lambda(A, B) = 0$ ($n > 0$). The natural isomorphism $\text{Hom}_{\Lambda \otimes \Gamma}(A, \text{Hom}_\Sigma(B, C)) \cong \text{Hom}_{\Gamma \otimes \Sigma}(A \otimes_\Lambda B, C)$ then yields a spectral sequence

$\text{Ext}_{\Lambda \otimes \Gamma}^p(A, \text{Ext}_\Sigma^q(B, C)) \Rightarrow_p \text{Ext}_{\Gamma \otimes \Sigma}^n(A \otimes_\Lambda B, C)$ by the double complex argument in Section D.

The **homological dimension** $\text{hdim}_R A$, $\text{dh}_R A$, or **projective dimension** $\text{proj dim}_R A$ of $A \in {}_R \mathcal{M}$ is the supremum ($\leq \infty$) of n such that $\text{Ext}_R^n(A, B) \neq 0$ for some B . The relation $\text{hdim}_R A \leq 0$ means that A is projective. The **injective dimension** $\text{inj dim}_R B$ of $B \in {}_R \mathcal{M}$ is defined similarly by means of the functor $\text{Ext}_R^n(\cdot, B)$, and the **weak dimension** $\text{wdim}_R C$ of $C \in {}_R \mathcal{M}$ by the functor $\text{Tor}_n^R(\cdot, C)$. The common value $\sup\{\text{proj dim}_R A \mid A \in {}_R \mathcal{M}\} = \sup\{\text{inj dim}_R B \mid B \in {}_R \mathcal{M}\}$ is called the **left global dimension** $1 \text{ gl dim } R$ of R . It is identical with the supremum of homological dimensions of \dagger cyclic modules (M. Auslander, 1955). The **right global dimension** $\text{r gl dim } R$ is defined similarly. The common value $\sup\{\text{wdim}_R A \mid A \in \mathcal{M}_R\} = \sup\{\text{wdim}_R C \mid C \in {}_R \mathcal{M}\}$ is called the **weak global dimension** $\text{w gl dim } R$ of R . We have $\text{w gl dim } R \leq 1 \text{ gl dim } R$, $\text{r gl dim } R$. The equality may fail to hold (Kaplansky, 1958). If R is \dagger Noetherian, the three global dimensions coincide (Auslander, 1955) and are called simply the **global dimension** of R : $\text{gl dim } R$. The condition $1 \text{ gl dim } R = 0$ (or $\text{r gl dim } R = 0$) holds if and only if R is an \dagger Artinian semi-simple ring, while $\text{w gl dim } R = 0$ if and only if R is a \dagger regular ring in the sense of J. von Neumann (M. Harada, 1956). A ring R is called **left (right) hereditary** if $1 \text{ gl dim } R \leq 1$ ($\text{r gl dim } R \leq 1$), and **left (right) semihereditary** if every finitely generated left (right) ideal is projective. A left and right (semi)hereditary ring is called a **(semi)hereditary ring**. Since projectivity and \dagger invertibility of an ideal of a (commutative) integral domain R are equivalent, R is hereditary if and only if R is a \dagger Dedekind ring. In this case, the projective class group of R reduces to the \dagger ideal class group. An integral domain R is semihereditary if and only if $\text{w gl dim } R \leq 1$ (A. Hattori, 1957), and in that case R is called a **Prüfer ring**. A \dagger maximal order over a Dedekind ring is hereditary. A commutative semihereditary ring R is characterized by the property that flatness of R -modules is equivalent to torsion-freeness (S. Endo, 1961). A Noetherian ring R is left self-injective if and only if R is \dagger quasi-Frobenius (M. Ikeda, 1952), and the global dimension of a quasi-Frobenius ring is 0 or ∞ (S. Eilenberg and T. Nakayama, 1955). A polynomial ring $R = K[X_1, \dots, X_n]$ over a commutative ring K satisfies $\text{gl dim } R = \text{gl dim } K + n$. When K is a field, this is a reformulation of Hilbert's theory of syzygy sequences (\rightarrow 369 Rings of Polynomials). In this sense, the study of the global dimension of rings and categories is sometimes called **syzygy theory** (Eilenberg, 1956). The homological algebra of commutative Noetherian rings has been studied extensively and

is useful in algebraic geometry. Since $\text{gl dim } R = \sup_m \text{gl dim } R_m$ (R_m is the \dagger ring of quotients relative to m), with m running over the maximal ideals of R , the problem of determining $\text{gl dim } R$ reduces to the case of \dagger local rings. A finitely generated flat module over a local ring R is free. If K denotes the residue field R/m , where m is the maximal ideal of the local ring R , $\text{Tor}^R(K, K)$ has the structure of a Hopf algebra (E. F. Assmus, Jr., 1959). Detailed results concerning the **Betti numbers** $\dim \text{Tor}_i^R(K, K)$ of R have been obtained (J. Tate, 1957, and others). In particular, R is \dagger regular if and only if $\text{gl dim } R < \infty$ (Serre, 1955). A local ring R is called a **Gorenstein ring** if the injective dimension of R -module R is finite. This is a notion intermediate between regular rings and \dagger Macaulay rings (\rightarrow 284 Noetherian Rings).

Consideration of a ring R in relation to a subring S leads to **relative homological algebra**. Foundations for this theory were established by Hochschild (1956). An exact sequence of R -modules that \dagger splits as a sequence of S -modules is called an **(R, S) -exact sequence**. An R -module P is called an **(R, S) -projective module** if $\text{Hom}_R(P, \cdot)$ maps any (R, S) -exact sequence to an exact sequence. **(R, S) -injective modules** are defined similarly. Based on these notions, $\text{Ext}_{(R, S)}^i$ and $\text{Tor}^{(R, S)}$ are defined as the **relative derived functors** of Hom_R and \otimes_R , respectively. We also have a relative theory from a different viewpoint (S. Takasu, 1957). Relative theory is extended to general categories from various viewpoints [6, 14] (\rightarrow Section Q).

L. Cohomology Theory for Associative Algebras

Let Λ be an \dagger algebra over a commutative ring K and A a \dagger two-sided Λ -module. Let C^n be the module of all n -linear mappings of Λ into A called **n -cochains** ($C^0 = A$). Define the coboundary operator $\delta^n: C^n \rightarrow C^{n+1}$ by $(\delta^n f)(\lambda_1, \dots, \lambda_{n+1}) = \lambda_1 f(\lambda_2, \dots, \lambda_{n+1}) + \sum_{i=1}^n (-1)^i f(\lambda_1, \dots, \lambda_i \lambda_{i+1}, \dots, \lambda_{n+1}) + (-1)^{n+1} f(\lambda_1, \dots, \lambda_n) \lambda_{n+1}$. We thus obtain a complex whose cohomology is denoted by $H^n(\Lambda, A)$ and is called the **n th Hochschild's cohomology group** of Λ relative to the **coefficient module** A (Hochschild, 1945). A cochain f is called **normalized** if $f(\lambda_1, \dots, \lambda_n) = 0$ whenever one of the λ_i is 1. We obtain the same cohomology group $H^n(\Lambda, A)$ from the subcomplex of normalized cochains. $\{H^n(\Lambda, \cdot)\}$ is a cohomological functor from the category ${}_{\Lambda}\mathcal{M}_{\Lambda}$ of two-sided Λ -modules to the category ${}_K\mathcal{M}$. Using the **enveloping algebra** $\Lambda^e = \Lambda \otimes_K \Lambda^0$, where Λ^0 is an anti-isomorphic

copy of Λ , ${}_{\Lambda}\mathcal{M}_{\Lambda}$ can be identified with ${}_{\Lambda^e}\mathcal{M}$ (and \mathcal{M}_{Λ^e}). If Λ is K -projective, $\{H^n(\Lambda, \cdot)\}$ is isomorphic to $\{\text{Ext}_{\Lambda^e}^n(\Lambda, \cdot)\}$. (In [2], $H^n(\Lambda, A)$ is defined as $\text{Ext}_{\Lambda^e}^n(\Lambda, A)$ in general.) We have $H^0(\Lambda, A) = \{a \in A \mid \lambda a = a\lambda, \forall \lambda \in \Lambda\}$. We call 1-cocycles **derivations** (or **crossed homomorphisms**) of Λ in A and 1-coboundaries **inner derivations**. Thus $H^1(\Lambda, A)$ is the derivation class group and is related to the \dagger ramification. When K is a field, $H^1(\Lambda, \cdot) = 0$ if and only if Λ is a \dagger separable algebra. In general, an algebra Λ over a commutative ring K is called a **separable algebra** if Λ is Λ^e -projective, i.e., if $\text{Ext}_{\Lambda^e}^1(\Lambda, \cdot) = 0$ (Auslander and O. Goldman, 1960). This is a generalization of the notion of \dagger maximally central algebras (Nakayama and G. Azumaya, 1948). We have a one-to-one correspondence of $H^2(\Lambda, A)$ to the family of **algebra extensions** of Λ with kernel A (i.e., K -algebras Γ containing A as a two-sided ideal such that $\Gamma/A = \Lambda$) satisfying $A^2 = 0$. Any extension of an algebra Λ over a field K such that $H^2(\Lambda, \cdot) = 0$ splits over a nilpotent kernel (J. H. C. Whitehead and G. Hochschild). This holds in particular for a separable algebra, and we obtain the \dagger Wedderburn-Mal'tsev theorem. There are some interpretations of $H^3(\Lambda, A)$ in terms of extensions.

The supremum (\leq) of n such that $H^n(\Lambda, A) \neq 0$ for some A is called the **cohomological dimension** of Λ and written $\dim \Lambda$. For a finite-dimensional algebra Λ over a field K , $\dim \Lambda < \infty$ if and only if Λ/N is separable and $\text{gl dim } \Lambda < \infty$, where N is the \dagger radical of Λ (N. Ikeda, H. Nagao, and Nakayama, 1954).

The homology groups $H_n(\Lambda, A)$ of Λ relative to a coefficient module A are defined similarly. If Λ is K -projective, $\{H_n(\Lambda, \cdot)\}$ is isomorphic to $\{\text{Tor}_n^{\Lambda^e}(\cdot, \Lambda)\}$.

M. Cohomology of Groups

The pair consisting of an algebra Λ over K and an algebra homomorphism $\varepsilon: \Lambda \rightarrow K$ is called a **supplemented algebra** [2] (or **augmented algebra** [6]), of which ε is the **augmentation**. The \dagger group algebra $\mathbf{Z}[G]$ of a group G over the ring of rational integers is a supplemented algebra, in which the augmentation is defined by $\varepsilon(x) = 1$ ($x \in G$). The category of left G -modules is identified with the category of left $\mathbf{Z}[G]$ -modules. For a finite group G , a finitely generated projective G -module is not necessarily free (D. S. Rim, 1959) and is isomorphic to the direct sum of a free module and a left ideal of $\mathbf{Z}[G]$. It follows that the projective class group of $\mathbf{Z}[G]$ is a finite group (R. G. Swan, 1960). The **cohomology groups** and **homology groups** of G relative to $A \in {}_G\mathcal{M}$ (Eilenberg and S. MacLane, 1943) are defined

by $H^n(G, A) = \text{Ext}_{\mathbb{Z}[G]}^n(\mathbb{Z}, A)$ and $H_n(G, A) = \text{Tor}_{\mathbb{Z}[G]}^n(\mathbb{Z}, A)$, respectively. Their concrete description is given usually via the $\mathbb{Z}[G]$ -standard resolution of \mathbb{Z} .

(1) **Homogeneous formulation.** The group of **homogeneous n -chains** is the free Abelian group with basis $G \times \dots \times G$ ($n+1$ times), on which G operates by $x(x_0, \dots, x_n) = (xx_0, \dots, xx_n)$, and the boundary operator is defined by $d(x_0, \dots, x_n) = \sum_{i=0}^n (-1)^i (x_0, \dots, \hat{x}_i, \dots, x_n)$.

(2) **Nonhomogeneous formulation.** The group of **nonhomogeneous n -chains** is the $\mathbb{Z}[G]$ -free module with basis $G \times \dots \times G$ (n times), and the boundary operator is defined by $d(x_1, \dots, x_n) = x_1(x_2, \dots, x_n) + \sum_{i=1}^n (-1)^i (x_1, \dots, x_i x_{i+1}, \dots, x_n) + (-1)^n (x_1, \dots, x_{n-1})$. A nonhomogeneous 2-cocycle is sometimes called a **factor set**. $H^0(G, A)$ is the submodule A^G of A consisting of the G -invariant elements, while $H_0(G, A)$ is the largest residue class module A_G of A on which G acts trivially. Given two groups G and K , an exact sequence of group homomorphisms $1 \rightarrow K \rightarrow E \rightarrow G \rightarrow 1$ is called a **group extension** of G over the kernel K . When K is Abelian, the extension canonically induces a G -module structure on K , and the deviation of K from being a semidirect factor of E is measured by a factor set. The group $H^2(G, A)$ is thus in one-to-one correspondence with the set of equivalence classes of the \dagger group extensions of G over A which induce the originally given G -module structure on A (\rightarrow 190 Groups N). This point of view is essential in the proof of the \dagger Schur-Zassenhaus theorem (\rightarrow 151 Finite Groups). $H^3(G, A)$ is interpreted as the set of obstructions for extensions (Eilenberg and MacLane, 1947). For a \dagger free group F , $H^n(F, A) = 0$ ($n > 1$). If a group G is represented as a factor group F/R of a free group F , we have a group extension $1 \rightarrow K \rightarrow E \rightarrow G \rightarrow 1$, where $K = R/[R, R]$ and $E = F/[R, R]$. Let $\xi \in H^2(G, K)$ correspond to this extension. Then for any G -module A , the cup product $\chi \rightarrow \chi \smile \xi$ followed by the pairing $\text{Hom}(K, A) \otimes K \rightarrow A$ provides isomorphisms $H^n(G, \text{Hom}(K, A)) \cong H^{n+2}(G, A)$ ($n > 0$) (the **cup product reduction theorem** of Eilenberg and MacLane, 1947); similarly, we have the reduction theorem for the homology. The \mathbb{Z} -algebra $H(G, \mathbb{Z}) = \sum_{n=0}^{\infty} H^n(G, \mathbb{Z})$ under the multiplication defined by the cup product is finitely generated if G is a finite group (B. B. Venkov, 1959; L. Evens, 1961).

The following are mappings relative to a subgroup H .

(1) The inner automorphism by $x \in G$ induces an isomorphism of $H^n(H, A)$ and $H^n(xHx^{-1}, A)$ which reduces to the identity of $H^n(G, A)$ if $H = G$. Hence if H is a normal subgroup, $H^n(H, A)$ has the structure of a G/H -module, and similarly for $H_n(H, A)$.

(2) When H is a normal subgroup of G , the mapping $(x_1, \dots, x_n) \rightarrow (x_1 H, \dots, x_n H)$ of nonhomogeneous chains induces the **inflation** (or **lift**) $\text{Inf}: H^n(G/H, A^H) \rightarrow H^n(G, A)$ and the **deflation** $\text{Def}: H_n(G, A) \rightarrow H_n(G/H, A_H)$.

(3) The embedding of nonhomogeneous chains induces the **restriction** $\text{Res}: H^n(G, A) \rightarrow H^n(H, A)$ and the **injection** Inj (or **corestriction** Cor): $H_n(H, A) \rightarrow H_n(G, A)$. The theory of \dagger induced representation gives another construction of these mappings; that is, if we put $\iota^G(A) = \text{Hom}_{\mathbb{Z}[H]}(\mathbb{Z}[G], A)$, Res is obtained by the isomorphism $H^n(G, \iota^G(A)) \cong H^n(H, A)$ combined with the homomorphism induced by $A \rightarrow \iota^G(A)$; while if we put $\iota_G(A) = \mathbb{Z}[G] \otimes_{\mathbb{Z}[H]} A$, Inj is obtained by the isomorphism $H_n(H, A) \cong H_n(G, \iota_G(A))$ followed by the homomorphism induced by $\iota_G(A) \rightarrow A$.

(4) If $(G: H) < \infty$, we have $\iota^G(A) \cong \iota_G(A)$. The composition of $H^n(H, A) \rightarrow H^n(G, \iota_G(A)) \rightarrow H^n(G, A)$ defines on the cohomology groups the $\text{Inj}: H^n(H, A) \rightarrow H^n(G, A)$, while the composition $H_n(G, A) \rightarrow H_n(G, \iota^G(A)) \rightarrow H_n(H, A)$ gives the $\text{Res}: H_n(G, A) \rightarrow H_n(H, A)$. In particular, $\text{Res}: H_1(G, \mathbb{Z}) \rightarrow H_1(H, \mathbb{Z})$ coincides with the \dagger transfer $G/[G, G] \rightarrow H/[H, H]$.

(5) Let H be a normal subgroup of G . Consider the additive relation ρ (the correspondence) between $h \in Z^n(H, A)^G$ and $f \in Z^{n+1}(G/H, A^H)$ determined by $\rho(h, f)$ if and only if there exists a $g \in C^n(G, A)$ such that $h = \text{Res } g$ and $\text{Inf } f = \delta g$. If the relation induces a homomorphism $H^n(H, A)^G \rightarrow H^{n+1}(G/H, A^H)$, then it is called the **transgression**. If $H^i(H, A) = 0$ ($0 < i < n$), the sequence $0 \rightarrow H^n(G/H, A^H) \rightarrow H^n(G, A) \rightarrow H^n(H, A)^G \rightarrow H^{n+1}(G/H, A^H) \rightarrow H^{n+1}(G, A)$ composed of inflation, restriction, and transgression mappings is exact (Hochschild and Serre, 1953) and is called the **fundamental exact sequence**. This exact sequence can be derived from a certain spectral sequence $H^n(G/H, H^q(H, A)) \Rightarrow_p H^n(G, A)$ (R. C. Lyndon, 1948; Hochschild and Serre, 1953).

The relative (co)homology theory relative to a subgroup (I. T. Adamson, 1954) can be dealt with in terms of the relative Ext and the relative Tor (Hochschild, 1956). Many results in the absolute case are generalized to the relative case: for example, the fundamental exact sequence (Nakayama and Hattori, 1958). The relative theory is further generalized to the cohomology theory of \dagger permutation representations of G (E. Snapper, 1964).

Non-Abelian Cohomology. For a non-Abelian G -group A , the cohomology "set" $H^1(G, A)$ (and $H^0(G, A)$) is defined as in the Abelian case by means of the nonhomogeneous cochains (\rightarrow e.g., [9]). Some efforts are being made toward the construction of a more general non-

Abelian theory (J. Giraud, *Cohomologie non abélienne*, Springer, 1971).

N. Finite Groups

Let G be a finite group and A a G -module. Define the norm $N: A \rightarrow A$ by $N(a) = \sum_{x \in G} xa$, and denote $\text{Ker } N$ by ${}_N A$. The kernel of the augmentation $\varepsilon: \mathbb{Z}[G] \rightarrow \mathbb{Z}$ is denoted by I . Put $\hat{H}^n(G, A) = H^n(G, A)$ ($n > 0$), $\hat{H}^0(G, A) = A^G / NA$, $\hat{H}^{-1}(G, A) = {}_N A / IA$, and $\hat{H}^{-n}(G, A) = H_{n-1}(G, A)$ ($n > 1$). Then $\{\hat{H}^n(G, \cdot)\}$ forms a cohomological functor, called the **Tate cohomology** (E. Artin and J. T. Tate), that can be described as the set of cohomology groups concerning a certain complex called a **complete free resolution** of \mathbb{Z} . (Similar arguments are valid more generally for quasi-Frobenius rings (Nakayama, 1957), and a theory of this kind is called **complete cohomology theory**.) We have $\hat{H}^n(G, A) = 0$ ($n \in \mathbb{Z}$) if and only if $\text{h dim}_{\mathbb{Z}[G]} A \leq 1$ (Nakayama, 1957). If A satisfies the conditions (i) $\hat{H}^1(G_p, A) = 0$ for any Sylow p -subgroup G_p of G , and (ii) there exists a $\xi \in \hat{H}^2(G, A)$ such that $\text{Res } \xi \in \hat{H}^2(G_p, A)$ has the same order as G_p and generates all of $\hat{H}^2(G_p, A)$, then the homomorphisms $\hat{H}^n(H, B) \rightarrow \hat{H}^{n+2}(H, A \otimes B)$ ($n \in \mathbb{Z}$) defined by the cup product with $\text{Res } \xi$ are isomorphisms for every subgroup H and every G -module B such that $\text{Tor}(A, B) = 0$ (Nakayama, 1957; for $B = \mathbb{Z}$, Tate, 1952). If G is cyclic, the mappings $\hat{H}^n(A) \rightarrow \hat{H}^{n+2}(A)$ ($n \in \mathbb{Z}$) defined by the cup product with a generator of $\hat{H}^2(\mathbb{Z})$ are isomorphisms. (The notation is abbreviated by omitting G .) If the orders of $\hat{H}^0(A)$ and $\hat{H}^1(A)$ are finite, their ratio is called the **Herbrand quotient** $h(A)$ of A . If $0 \rightarrow A' \rightarrow A \rightarrow A'' \rightarrow 0$ is exact, then $h(A) = h(A')h(A'')$. If A is finite, then $h(A) = 1$. By combining these two facts we obtain **Herbrand's lemma**: If A' is a G -submodule of A of finite index and $h(A')$ exists, then $h(A)$ also exists and $h(A) = h(A')$. The periodicity $\hat{H}^n(A) = \hat{H}^{n+p}(A)$ ($n \in \mathbb{Z}$, $A \in {}_G \mathcal{M}$) holds if and only if every Sylow subgroup is cyclic or a \dagger generalized quaternion group (Artin and Tate; [2]).

Let L/K be a finite \dagger Galois extension with the \dagger Galois group G . The cohomology groups of various types of G -modules related to L/K are called the **Galois cohomology groups** (\rightarrow 172 Galois Theory). Using **continuous cocycles**, a cohomology theory (**Tate cohomology**) is developed for infinite Galois extensions as well [9, 10]. By means of Galois cohomology (\rightarrow 59 Class Field Theory), the cohomology theory of finite groups and of \dagger totally disconnected compact groups (which are \dagger profinite groups) plays an important role in class field theory and its related areas.

O. Cohomology Theory of Lie Algebras

Let \mathfrak{g} be a \dagger Lie algebra over a commutative ring K , and assume that \mathfrak{g} is K -free. The \dagger enveloping algebra $U = U(\mathfrak{g})$ is a \dagger supplemented algebra over K . For a \mathfrak{g} -module ($= U$ -module) A , $\text{Ext}_U^n(K, A)$ and $\text{Tor}_n^U(K, A)$ are called the **cohomology groups** $H^n(\mathfrak{g}, A)$ and **homology groups** $H_n(\mathfrak{g}, A)$, respectively, of \mathfrak{g} relative to the coefficient module A . They are usually described by means of the U -free resolution $U \otimes \wedge_K(\mathfrak{g})$ of K (called the **standard complex** of \mathfrak{g}) constructed by C. Chevalley and Eilenberg (1948), where $\wedge_K(\mathfrak{g})$ is the exterior algebra of the K -module \mathfrak{g} and (denoting $1 \otimes (x_1 \wedge \dots \wedge x_n)$ by (x_1, \dots, x_n)) the differentiation is given by

$$d(x_1, \dots, x_n) = \sum_{i=1}^n (-1)^{i+1} x_i(x_1, \dots, \hat{x}_i, \dots, x_n) + \sum_{1 \leq i < j \leq n} (-1)^{i+j} ([x_i, x_j], x_1, \dots, \hat{x}_i, \dots, \hat{x}_j, \dots, x_n).$$

For $n > [\mathfrak{g}: K]$, $H^n(\mathfrak{g}, A) = H_n(\mathfrak{g}, A) = 0$. If \mathfrak{g} is a \dagger semisimple Lie algebra over a field K of characteristic 0, we have $H^1(\mathfrak{g}, A) = 0$, $H^2(\mathfrak{g}, A) = 0$, while $H^3(\mathfrak{g}, K) \neq 0$. $H^1(\mathfrak{g}, A) = 0$ is equivalent to Weyl's theorem, which asserts the complete reducibility of finite-dimensional representations (\rightarrow 248 Lie Algebras E). $H^2(\mathfrak{g}, A)$ and $H^3(\mathfrak{g}, A)$ are interpreted by means of Lie algebra extensions as in the cohomology of groups. The theorem on \dagger Levi decomposition is derived from $H^2(\mathfrak{g}, A) = 0$. Chevalley and Eilenberg constructed this cohomology by algebraization of the cohomology of compact \dagger Lie groups. They also introduced the notion of relative cohomology groups $H^n(\mathfrak{g}, \mathfrak{h}, A)$ relative to a Lie subalgebra \mathfrak{h} of \mathfrak{g} , which correspond to the cohomology of homogeneous spaces. $H^n(\mathfrak{g}, \mathfrak{h}, A)$ does not always coincide with $\text{Ext}_{U(\mathfrak{g}), U(\mathfrak{h})}^n(K, A)$ (Hochschild, 1956), but does so in an important case where K is a field of characteristic 0 and \mathfrak{h} is \dagger reductive in \mathfrak{g} (\rightarrow 248 Lie Algebras).

For \dagger transformation spaces of \dagger linear algebraic groups G over a field K , the **rational cohomology groups** are introduced using the notion of **rational injectivity** (Hochschild, 1961). In particular, if G is a \dagger unipotent algebraic group over a field K of characteristic 0, then $H(G, A)$ is isomorphic to $H(\mathfrak{g}, A)$, where \mathfrak{g} is the Lie algebra of G . There is also a relative theory.

P. Amitsur Cohomology

Let R be a commutative ring, and F a covariant functor from the category \mathcal{C}_R of com-

mutative R -algebras to the category of Abelian groups. For $S \in \mathcal{C}_R$ and $n = 0, 1, 2, \dots$, we write $S^{(n)} = S \otimes \dots \otimes S$ (n -fold tensor product over R). Let $\varepsilon_i: S^{(n+1)} \rightarrow S^{(n+2)}$ ($i = 0, 1, \dots, n+1$) be \mathcal{C}_R -morphisms defined by $\varepsilon_i(x_0 \otimes \dots \otimes x_n) = x_0 \otimes \dots \otimes x_{i-1} \otimes 1 \otimes x_i \otimes \dots \otimes x_n$. Defining $d^n: F(S^{(n+1)}) \rightarrow F(S^{(n+2)})$ by $d^n = \sum_{i=0}^{n+1} (-1)^i F(\varepsilon_i)$, we obtain a cochain complex $\{F(S^{(n+1)}), d^n\}$. This complex and its cohomology groups are called the **Amitsur complex** and the **Amitsur cohomology groups**, and are usually denoted by $C(S/R, F)$ and $H^n(S/R, F)$, respectively.

If S/R is a finite Galois extension with Galois group G , then the group $H^n(S/R, U)$ of the unit group functor U is naturally isomorphic to $H^n(G, U(S))$. If S/R is a finite purely inseparable extension, then $H^n(S/R, U) = 0$ for $n \geq 3$. The group $H^2(S/R, U)$ is related to the Brauer group $B(S/R)$ (\rightarrow 29 Associative Algebras K).

Q. Relative Theory

In the course of the development of homological algebra, it has been recognized that the notion of projective (resp. injective) resolutions should be generalized ([14, 4]; Hochschild, 1956). In the meantime, a method has been introduced that utilizes simplicial objects in order to define the derived functor of an arbitrary functor with Abelian category as its range ([15, 17]; J. Beck, 1967). As a consequence of these developments, there emerged a viewpoint, which we describe below, making it possible to unify various known definitions of (co-)homology theories that has been designed for particular cases.

Let \mathcal{A} be a category and \mathcal{P} a class of objects in \mathcal{A} . In this section, we denote the set $\text{Hom}_{\mathcal{A}}(A, B)$ of morphisms by $\mathcal{A}(A, B)$. A morphism $f: A \rightarrow B$ in \mathcal{A} is called a **\mathcal{P} -epimorphism** if the induced mapping $\mathcal{A}(P, f)$ ($= \text{Hom}(P, f): \mathcal{A}(P, A) \rightarrow \mathcal{A}(P, B)$) is surjective for any $P \in \mathcal{P}$. The class \mathcal{P} is called a **projective class** in \mathcal{A} if there exist an object $P \in \mathcal{P}$ and a \mathcal{P} -epimorphism $f: P \rightarrow A$ for each object $A \in \mathcal{A}$. To any category \mathcal{A} , we associate a preadditive category $\mathbf{Z}\mathcal{A}$, adding a zero object to \mathcal{A} if necessary: Put $\text{Ob } \mathbf{Z}\mathcal{A} = \text{Ob } \mathcal{A}$, $\mathbf{Z}\mathcal{A}(A, B) = \text{free Abelian group generated by the set } \mathcal{A}(A, B)$. \mathcal{A} is regarded as a subcategory of $\mathbf{Z}\mathcal{A}$ by the natural inclusion $J: \mathcal{A} \rightarrow \mathbf{Z}\mathcal{A}$. Any functor T from \mathcal{A} into an Abelian category \mathcal{B} has a unique additive extension $\bar{T}: \mathbf{Z}\mathcal{A} \rightarrow \mathcal{B}$ such that $T = \bar{T}J$. If \mathcal{A} is an additive category, there is a canonical projection $\theta: \mathbf{Z}\mathcal{A} \rightarrow \mathcal{A}$ such that $\theta J = \text{Id}$. If furthermore T is additive, then $\bar{T} = T\theta$.

Now suppose that a projective class \mathcal{P} in \mathcal{A} is given. For $A \in \mathcal{A}$, an augmented chain com-

plex $X \rightarrow A$ in $\mathbf{Z}\mathcal{A}$,

$$\rightarrow X_n \xrightarrow{d_n} X_{n-1} \rightarrow \dots \xrightarrow{d_1} X_0 \xrightarrow{d_0} A, \quad d_i d_{i+1} = 0,$$

is called a **\mathcal{P} -projective resolution** of A if (i) $X_n \in \mathcal{P}$ ($n \geq 0$), and (ii) it is **\mathcal{P} -acyclic** (i.e., the sequence

$$\begin{aligned} \rightarrow \mathbf{Z}\mathcal{A}(P, X_n) \xrightarrow{d_n} \mathbf{Z}\mathcal{A}(P, X_{n-1}) \rightarrow \dots \\ \xrightarrow{d_1} \mathbf{Z}\mathcal{A}(P, X_0) \xrightarrow{d_0} \mathbf{Z}\mathcal{A}(P, A) \rightarrow 0 \end{aligned}$$

is exact for any $P \in \mathcal{P}$ [16]). Note that the \mathcal{P} -acyclicity in this case implies the existence of a contracting homotopy

$$\begin{aligned} h_n: \mathbf{Z}\mathcal{A}(P, X_n) \rightarrow \mathbf{Z}\mathcal{A}(P, X_{n+1}), \\ n \geq -1, X_{-1} = A, \end{aligned}$$

satisfying $d_{n+1}h_n + h_{n-1}d_n = 1$.

Comparison theorem: Given two \mathcal{P} -projective resolutions $X \rightarrow A$ and $Y \rightarrow A$, we have that the chain complexes X , and Y , are chain equivalent in $\mathbf{Z}\mathcal{A}$.

Let $T: \mathcal{A} \rightarrow \mathcal{B}$ be a (covariant) functor with \mathcal{B} an Abelian category. The n th **left derived functor** $L_n T: \mathcal{A} \rightarrow \mathcal{B}$ ($n \geq 0$) of T , with respect to \mathcal{P} , is defined by $L_n T(A) = H_n(\bar{T}X)$ for a \mathcal{P} -projective resolution $X \rightarrow A$. The derived functors $L_n T$ will remain unaffected if we replace the projective class \mathcal{P} by its enlargement $\bar{\mathcal{P}} = \{\text{objects in } \mathcal{P} \text{ together with their retracts}\}$.

We can easily verify that (i) $L_0 T(P) = T(P)$ and $L_n T(P) = 0$ ($n > 0$) for $P \in \mathcal{P}$, and (ii) a short exact sequence $0 \rightarrow T' \rightarrow T \rightarrow T'' \rightarrow 0$ of functors $\mathcal{A} \rightarrow \mathcal{B}$ induces a long exact sequence of derived functors

$$\begin{aligned} \rightarrow L_n T' \rightarrow L_n T \rightarrow L_n T'' \xrightarrow{\partial} L_{n-1} T' \rightarrow \dots \\ \rightarrow L_0 T'' \rightarrow 0. \end{aligned}$$

If \mathcal{A} is preadditive and has a zero object and kernels, then it is routine to give a \mathcal{P} -projective resolution of any object. If \mathcal{A} has finite \dagger limits (i.e., \dagger finite products and \dagger equalizers), it can be proved that there exists a \mathcal{P} -projective resolution for any object [17].

There is a standard functorial construction which provides canonically a projective class \mathcal{P} in a category \mathcal{A} and a \mathcal{P} -projective resolution of any object in \mathcal{A} . Let (G, ε, δ) be a **cotriple** (or **comonad** [18] or functor coalgebra) in \mathcal{A} . Here $G: \mathcal{A} \rightarrow \mathcal{A}$ is an endofunctor, $\varepsilon: G \rightarrow \text{Id}$ and $\delta: G \rightarrow G^2 = GG$ are natural transformations such that $G\varepsilon \circ \delta = \varepsilon G \circ \delta = 1_G$ and $G\delta \circ \delta = \delta G \circ \delta$. A cotriple comes usually from a pair (F, U) of \dagger adjoint functors $U: \mathcal{A} \rightarrow \mathcal{C}$, $F: \mathcal{C} \rightarrow \mathcal{A}$ with natural bijection $\lambda: \mathcal{A}(F(C), A) \cong \mathcal{C}(C, U(A))$. Putting $G = FU: \mathcal{A} \rightarrow \mathcal{A}$, $\varepsilon(A) = \lambda^{-1}(1_{U(A)}): FU(A) \rightarrow A$, $\eta(C) = \lambda(1_{F(C)}): C \rightarrow UF(C)$, we have a cotriple $(G = FU, \varepsilon, \delta = F\eta U)$ in \mathcal{A} . Conversely, it is known that any cotriple in \mathcal{A} is induced from a suitable pair of adjoint functors.

Given a cotriple (G, ε, δ) in \mathcal{A} , we define a projective class $\mathcal{P}_G = \{G(A) \mid A \in \mathcal{A}\}$ (or its enlargement $\bar{\mathcal{P}}_G$) in \mathcal{A} , and an augmented simplicial object $G_*(A) \rightarrow A$ for any object A as follows. Put $G_n(A) = G^{n+1}(A)$ ($n \geq 0$), $\partial_i = \partial_i^n = G^i \varepsilon G^{n-i}(A): G_n(A) \rightarrow G_{n-1}(A)$ (face operator) and $\delta_i = \delta_i^n = G^i \delta G^{n-i}(A): G_n(A) \rightarrow G_{n+1}(A)$ (degeneracy operator) for $0 \leq i \leq n$, $G_{-1}(A) = A$. Then $G_*(A) \rightarrow A$ gives rise to a \mathcal{P}_G (or equivalently $\bar{\mathcal{P}}_G$)-projective resolution of A in $\mathbf{Z}\mathcal{A}$ with differentials $d_n = \sum_{i=0}^n (-1)^i \partial_i$. This is the bar resolution (or standard resolution) in a generalized sense, and there are many (co-)homology theories defined by means of such constructions.

Most of the above definitions and constructions can be dualized so as to give **injective classes**, **\mathcal{I} -injective resolutions**, and **right derived functors** with respect to \mathcal{I} , **triples** (or **manads**), etc. (See also [19] for generalized (co-)homology).

201 (IX.6) Homology Theory

A. History

Homology theory is the oldest and most extensively developed portion of algebraic topology. Historically, it started with measuring the higher-dimensional **connectivity** of a space in the sense that the 0-dimensional connectivity is the number of connected components of the space. For example, take a 2-sphere S^2 and a 2-torus T^2 . Then T^2 is distinguished from S^2 by the fact that on T^2 a closed curve can be drawn without forming a boundary, while this is not true for S^2 . In fact, a curve (c_1 or c'_1 in Fig. 1) can be drawn on T^2 so that it does not form a boundary of an embedded 2-disk. On more complicated surfaces there are many kinds of such closed curves. The maximum number of such closed curves is the 1-dimensional connectivity of the surface; this is a topological property of the surface. For example, the 1-dimensional connectivity of S^2 is 0, that of T^2 is 2, and that of the surface in Fig. 2 is 6. A more general consideration of the bounding properties of q -dimensional closed submanifolds of a manifold led E. Betti (*Ann. Mat. Pure Appl.*, 4 (1871)) to introduce the notion of the q -dimensional connectivity of the manifold, which was a precursor of homology theory.

Fig. 1

Fig. 2

The foundation of homology theory was laid by H. Poincaré [1]. He started his study of homology with analytic treatment of manifolds, which led to a series of complications.

Poincaré then introduced a new method for the study, now called *combinatorial topology*: He decomposed the manifold into elementary pieces or *cells*, which adjoin one another in a regular fashion; he then substituted the algebraic notions of *cycles* and *boundary operators* for the geometrical notions of closed submanifolds and boundaries. Thereby the notion of homology groups acquired an exact logical meaning, and the fundamental formulas, which are now called *Poincaré formulas*, were proved.

After Poincaré, much of the development of homology theory centered around the question of the **topological invariance of homology groups**, that is, the independence of the homology groups on the choice of *cellular decomposition*. Through the development of *simplicial complexes* and their techniques, J. W. Alexander (*Trans. Amer. Math. Soc.*, 28 (1926)) gave the first fully satisfactory proof for topological invariance of the homology groups of *polyhedra*. In those days, the homology groups themselves were barely recognized; instead, one dealt with numerical invariants such as the *Betti numbers* and the *torsion coefficients* [2, 3].

During the period 1925–1935 there was a gradual shift of interest from the numerical invariants to the homology groups themselves, and homology theory developed intensively [4, 5]. S. Lefschetz (*Trans. Amer. Math. Soc.*, 28 (1926)) added the theory of the *intersection products* to the homology of manifolds. He also invented *relative homology theory* (*Proc. Nat. Acad. Sci. US*, 13 (1927)) and generalized the *duality theorems* of Poincaré and Alexander (*ibid.*, 15 (1929)). G. de Rham (*J. Math. Pures Appl.*, 10 (1931)) obtained a duality theorem that relates the *exterior differential forms* in a manifold to the homology groups of the manifold. L. S. Pontryagin (*Ann. Math.*, (2) 35 (1934)) proved the complete group-invariant form of the Alexander duality theorem. These duality theorems seemed to reflect the existence of a theory dual to homology theory, and the genesis of this dual theory, now called *cohomology*, occurred in 1935, in the work of Alexander and A. N. Kolmogorov. It was discovered subsequently by Alexander (*Ann. Math.*, (2) 37 (1936)), E. Čech (*ibid.*), and H. Whitney (*ibid.*, 39 (1938)) that the cohomology of a polyhedron can be made into a ring.

On the other hand, after L. Vietoris (*Math. Ann.*, 97 (1927)) and P. S. Aleksandrov (*Ann. Math.*, (2) 30 (1928)), many devices were invented to extend the homology theory of polyhedra to general *topological spaces*, and numerous variants of homology theory appeared at the hands of Čech (1932), Lefschetz

(1933), Alexander (1935), and Kolmogorov (1936). This development served to clarify the relations between combinatorial and set-theoretic methods in topology (\rightarrow 426 Topology), whereas it produced complexity and confusion in homology theory [6]. S. Eilenberg and N. E. Steenrod (*Proc. Nat. Acad. Sci. US*, 31 (1945) and [7]) cleared the air by treating homology axiomatically.

Roughly speaking, a homology theory assigns *Abelian groups* to *topological spaces* and *homomorphisms* to *continuous mappings* of one space to another. In this way, a homology theory is an algebraic image of topology; it converts topological problems to algebraic problems. Starting from this viewpoint, Eilenberg and Steenrod selected some fundamental properties as axioms to characterize homology theory. This unified homology theories and allowed systematic treatment of homological problems which had previously been done separately “by hand” in each case. Moreover, it motivated the birth of a new branch of mathematics, called *homological algebra*.

B. Homology of Chain Complexes

A **chain complex** $C = \{C_q, \partial_q\}$ is a collection of (additive) Abelian groups C_q , one for each integer q , and of homomorphisms $\partial_q: C_q \rightarrow C_{q-1}$ such that $\partial_q \circ \partial_{q+1} = 0$ for each q . Elements of C_q are called *q-chains* of C , and ∂_q is called the **boundary operator**. A **subcomplex** $C' = \{C'_q, \partial'_q\}$ of C is a chain complex such that $C'_q \subset C_q$ and $\partial'_q = \partial_q|_{C'_q}$ for each q .

The *kernel* of ∂_q is denoted by $Z_q(C)$, and its element is called a *q-cycle* of C . The *image* of ∂_{q+1} is denoted by $B_q(C)$, and its element is called a *q-boundary* of C . The relation $\partial_q \circ \partial_{q+1} = 0$ implies $B_q(C) \subset Z_q(C)$. The *quotient group* $Z_q(C)/B_q(C)$ is denoted by $H_q(C)$, the *qth homology group* of C . Elements of $H_q(C)$ are called *q-dimensional homology classes* of C . Two cycles representing the same homology class are said to be **homologous**. The *direct sum* $\sum_q H_q(C)$ is denoted by $H_*(C)$ and is called the **homology group** of C .

If $C = \{C_q, \partial_q\}$ and $C' = \{C'_q, \partial'_q\}$ are chain complexes, a **chain mapping (chain map)** $\varphi: C \rightarrow C'$ is a sequence of homomorphisms $\varphi_q: C_q \rightarrow C'_q$ such that $\partial'_q \circ \varphi_q = \varphi_{q-1} \circ \partial_q$ for each q . If $\varphi: C \rightarrow C'$ is a chain mapping, then φ_q sends $Z_q(C)$ to $Z_q(C')$ and $B_q(C)$ to $B_q(C')$, and hence φ induces a homomorphism of $H_q(C)$ to $H_q(C')$.

If $H_q(C)$ is *finitely generated*, it can be decomposed into the direct sum of a free Abelian group $B_q(C)$ and a finite Abelian group $T_q(C)$. $B_q(C)$ and $T_q(C)$ are called the *qth Betti group*

of C and the q th **torsion group** of C , respectively. The rank ρ_q of $B_q(C)$ is called the q th **Betti number** of C . $T_q(C)$ is isomorphic to the direct sum of $\tau(q)$ finite cyclic groups of orders $\theta_1^q, \theta_2^q, \dots, \theta_{\tau(q)}^q$, where $\theta_i^q > 1$ and θ_i^q divides θ_{i+1}^q for $i = 1, \dots, \tau(q) - 1$ (\rightarrow 2 Abelian Groups). The numbers $\theta_1^q, \theta_2^q, \dots, \theta_{\tau(q)}^q$ are called the q th **torsion coefficients** of C .

If $H_*(C)$ is finitely generated, then the number $\chi(C) = \sum_q (-1)^q \rho_q$ is called the **Euler number**, the **Euler characteristic**, or the **Euler-Poincaré characteristic** of C . In this case a \dagger polynomial $\sum_q \rho_q t^q$ with variable t is called the **Poincaré polynomial** of C .

Let C be a chain complex such that, for each q , C_q is a \dagger free Abelian group of finite \dagger rank. Then the q th Betti number and the q th torsion coefficients are well defined for each q . Denote the ranks of C_q and $B_q(C)$ by α_q and β_q , respectively. Then it holds that $\rho_q = \alpha_q - \beta_q - \beta_{q-1}$, and hence $\chi(C) = \sum_q (-1)^q \alpha_q$. (**Euler-Poincaré formula**). Moreover, there exists a set of bases, one for each C_q , with the following properties: For each q , the base for C_q is composed of five types of elements, a_i^q ($1 \leq i \leq \beta_q - \tau_q$), b_i^q ($1 \leq i \leq \tau_q$), c_i^q ($1 \leq i \leq \rho_q$), d_i^q ($1 \leq i \leq \tau_{q-1}$), and e_i^q ($1 \leq i \leq \beta_{q-1} - \tau_{q-1}$); ∂_q satisfies $\partial a_i^q = 0$, $\partial b_i^q = 0$, $\partial c_i^q = 0$, $\partial d_i^q = \theta_i^{q-1} b_i^{q-1}$, and $\partial e_i^q = a_i^{q-1}$. Such a set of bases is called the **canonical basis** of C .

Let C be a chain complex such that each C_q is a free Abelian group with a given base $\{\sigma_i^q\}$. Then the **incidence number** $[\sigma_i^q : \sigma_j^{q-1}] \in \mathbf{Z}$ is defined by $\partial_q(\sigma_i^q) = \sum_j [\sigma_i^q : \sigma_j^{q-1}] \sigma_j^{q-1}$. This notion was commonly used in the early days of topology.

C. Homology of Simplicial Complexes

Let K be a \dagger simplicial complex. An **oriented q -simplex** σ of K is a q -simplex $s \in K$ together with an equivalence class of \dagger total orderings of the vertices of s , two orderings being equivalent if they differ by an even permutation of the vertices. If a_0, \dots, a_q are the vertices of s , then $[a_0, a_1, \dots, a_q]$ denotes the oriented q -simplex of K consisting of the simplex s together with the equivalence class of the ordering $a_0 < a_1 < \dots < a_q$ of its vertices. For every vertex a of K there is a unique oriented 0-simplex $[a]$, and to every q -simplex with $q \geq 1$ there correspond exactly two oriented q -simplexes, which are said to be **opposites** of one another.

Let $C_q(K)$ denote the Abelian group generated by the oriented q -simplexes of K with the relations $\sigma + \sigma' = 0$ if σ' is the opposite of σ . If we choose an oriented q -simplex σ_i^q for each q -simplex s_i^q of K , then each element of $C_q(K)$ is written uniquely as a finite sum $\sum_i g_i \sigma_i^q$ with integers $g_i \neq 0$, and

$C_q(K)$ is a free Abelian group generated by the set $\{\sigma_i^q\}$. We define a homomorphism $\partial_q : C_q(K) \rightarrow C_{q-1}(K)$ by $\partial_q[a_0, a_1, \dots, a_q] = \sum_{i=0}^q (-1)^i [a_0, \dots, a_{i-1}, a_{i+1}, \dots, a_q]$. Then $\partial_q \circ \partial_{q+1} = 0$ holds, and we have a chain complex $C(K) = \{C_q(K), \partial_q\}$ ($C_q(K) = \{0\}$ if $q < 0$), called the **(oriented) simplicial chain complex**. The homology group $H_*(C(K))$ is denoted by $H_*(K)$ and is called the **(integral) homology group of the simplicial complex K** .

Let K_1 and K_2 be simplicial complexes, and let $f : K_1 \rightarrow K_2$ be a \dagger simplicial mapping. Then for each q , a homomorphism $f_{\#q} : C_q(K_1) \rightarrow C_q(K_2)$ can be defined by $f_{\#q}([a_0, a_1, \dots, a_q]) = [f(a_0), f(a_1), \dots, f(a_q)]$, where the right-hand side is understood to be 0 if $f(a_0), f(a_1), \dots, f(a_q)$ are not distinct. The sequence $f_{\#} = \{f_{\#q}\}$ is a chain mapping of $C(K_1)$ to $C(K_2)$, and it induces a homomorphism $f_* : H_*(K_1) \rightarrow H_*(K_2)$.

If K is a \dagger finite simplicial complex, then the Betti numbers, the torsion coefficients, and the Euler characteristic of K are defined to be those for the chain complex $C(K)$.

Let K_1 and K_2 be subcomplexes of a simplicial complex K . Then we have the following \dagger exact sequence which relates the homology group of $K_1 \cup K_2$ to the homology groups of K_1 , K_2 , and $K_1 \cap K_2$: $\dots \xrightarrow{\alpha} H_q(K_1 \cap K_2) \xrightarrow{\beta} H_q(K_1) + H_q(K_2) \xrightarrow{\gamma} H_q(K_1 \cup K_2) \xrightarrow{\delta} H_{q-1}(K_1 \cap K_2) \xrightarrow{\alpha} \dots$, where α , β , and δ_* are defined as follows. Let $i_l : K_l \cap K_2 \rightarrow K_1$ and $j_l : K_l \rightarrow K_1 \cup K_2$ ($l = 1, 2$) be inclusion mappings; then $\alpha(a) = (i_{1*}(a), -i_{2*}(a))$ and $\beta(a_1, a_2) = j_{1*}(a_1) + j_{2*}(a_2)$. If $z = c_1 + c_2$ ($c_i \in C(K_i)$) is a cycle of $C(K_1 \cup K_2)$ then $\partial(c_1) = -\partial(c_2)$ is a cycle of $C(K_1 \cap K_2)$; δ_* sends the homology class of z to the homology class of $\partial(c_1)$. The sequence is called the **Mayer-Vietoris exact sequence** of the couple $\{K_1, K_2\}$, and δ_* is referred to as the **connecting homomorphism**. The prototype of the Mayer-Vietoris exact sequence was obtained by W. Mayer (*Monatsh. Math. Phys.*, 36 (1929)) and L. Vietoris (*ibid.*, 37 (1930)). The present form is due to Eilenberg and Steenrod [7].

D. Homology of Polyhedra

If K is a \dagger simplicial complex and K' is a \dagger subdivision of K , then there exists a canonical isomorphism $H_*(K) \cong H_*(K')$. This proves that if K_1 and K_2 are \dagger simplicial decompositions of a \dagger polyhedron then $H_*(K_1)$ and $H_*(K_2)$ are isomorphic, because there exists a common subdivision of K_1 and K_2 . Thus we may define the **(integral) homology groups $H_*(X)$ of a polyhedron X** to be the homology group $H_*(K)$ of a simplicial decomposition K of X .

Let X and Y be polyhedra, and let $f : X \rightarrow Y$ be a continuous mapping. Take a \dagger simplicial approximation $\varphi : K \rightarrow L$ of f . Then a homo-

morphism of $H_*(X)$ to $H_*(Y)$ given by the induced homomorphism $\varphi_*: H_*(K) \rightarrow H_*(L)$ is independent of the choice of φ , and is denoted by f_* . The following properties hold: (i) $1_* = 1: H_*(X) \rightarrow H_*(X)$, where 1 is the identity; (ii) If $f: X \rightarrow Y$ and $g: Y \rightarrow Z$ are continuous mappings, then $(g \circ f)_* = g_* \circ f_*: H_*(X) \rightarrow H_*(Z)$; (iii) If $f, f': X \rightarrow Y$ are homotopic, then $f_* = f'_*: H_*(X) \rightarrow H_*(Y)$. These imply the **homotopy invariance of the homology group** stated as follows: If X and Y are polyhedra which are \dagger homotopy equivalent, then $H_*(X)$ and $H_*(Y)$ are isomorphic. Specifically, the homology group is a topological invariant. Thus if X is a \dagger triangulable space (for example, if X is a \dagger differentially manifold), then its homology group $H_*(X)$ can be defined to be the homology group $H_*(K)$, where (K, t) is a \dagger triangulation of X . This homology group is referred to as the **simplicial homology group** of X . Similarly, if X is a compact triangulable space, the Betti numbers $\rho_q(X)$ of X , etc. can be defined to be those for the chain complex $C(K)$.

If we denote by pt a single point, then $H_0(pt) = \mathbb{Z}$ (the group of integers) and $H_q(pt) = 0$ if $q \neq 0$. For an n -sphere S^n , a 2-torus T^2 , and a \dagger real projective plane P^2 , the homology groups can be computed as follows by means of their triangulations: (1) $H_0(S^n) \cong H_n(S^n) \cong \mathbb{Z}$, and $H_q(S^n) = 0$ if $q \neq 0, n$; (2) $H_0(T^2) \cong H_2(T^2) \cong \mathbb{Z}$, $H_1(T^2) \cong \mathbb{Z} + \mathbb{Z}$, and $H_q(T^2) = 0$ if $q \neq 0, 1, 2$; (3) $H_0(P^2) \cong \mathbb{Z}$, $H_1(P^2) \cong \mathbb{Z}_2$, and $H_q(P^2) = 0$ if $q \neq 0, 1$, where $\mathbb{Z}_2 = \mathbb{Z}/2\mathbb{Z}$.

Two surfaces are homeomorphic if and only if their integral homology groups are isomorphic (\rightarrow 410 Surfaces).

E. Singular Homology

There are various devices for defining homology groups of general topological spaces. A familiar one is the **singular homology theory** initiated by S. Lefschetz (*Bull. Amer. Math. Soc.*, 39 (1933)) and improved by S. Eilenberg (*Ann. Math.*, (2) 45 (1944)).

The **standard q -simplex** is the convex set $\Delta^q \subset \mathbb{R}^{q+1}$ consisting of all $(q+1)$ -tuples (t_0, t_1, \dots, t_q) of real numbers with $t_i \geq 0$, $t_0 + t_1 + \dots + t_q = 1$. Any continuous mapping of Δ^q to a topological space X is called a **singular q -simplex** in X . The i th **face** of a singular q -simplex $\sigma: \Delta^q \rightarrow X$ is the singular $(q-1)$ -simplex $\sigma \circ \varepsilon_i: \Delta^{q-1} \rightarrow X$, where the linear embedding $\varepsilon_i: \Delta^{q-1} \rightarrow \Delta^q$ is defined by $\varepsilon_i(t_0, \dots, t_{i-1}, t_{i+1}, \dots, t_q) = (t_0, \dots, t_{i-1}, 0, t_{i+1}, \dots, t_q)$.

For each integer q , let $S_q(X)$ denote the free Abelian group generated by the singular q -simplexes in X ($S_q(X) = 0$ if $q < 0$), and define a homomorphism $\partial_q: S_q(X) \rightarrow S_{q-1}(X)$ by $\partial_q(\sigma) =$

$\sum_{i=0}^q (-1)^i \sigma \circ \varepsilon_i$. Then we have a chain complex $S(X) = \{S_q(X), \partial_q\}$, called the **singular chain complex** of X . The homology group $H_*(S(X))$ is denoted by $H_*(X)$ and is called the **integral singular homology group** of the topological space X .

Given a continuous mapping $f: X \rightarrow Y$, a chain mapping $f_*: S(X) \rightarrow S(Y)$ is defined by sending each singular simplex $\sigma: \Delta^q \rightarrow X$ to the singular simplex $f \circ \sigma: \Delta^q \rightarrow Y$, and it induces the homomorphism $f_*: H_*(X) \rightarrow H_*(Y)$. The properties (i), (ii), (iii) of f_* in Section D hold for continuous mappings of topological spaces, and hence the singular homology group is a homotopy invariant.

The homology group $H_*(K)$ of a simplicial complex K is isomorphic to the singular homology group $H_*(|K|)$ of the polyhedron $|K|$. Therefore the simplicial homology group of a triangulable space is isomorphic to the singular homology group of the space.

If $\{X_i\}$ is the set of \dagger arcwise connected components of a topological space X , then $H_*(X) \cong \sum_i H_*(X_i)$. If X is arcwise connected, then $H_0(X) \cong \mathbb{Z}$. If $\{A_\lambda\}$ is the collection of all the compact subsets of X directed by inclusion, then $H_*(X)$ is isomorphic to the \dagger inductive limit $\varinjlim H_*(A_\lambda)$. It is not true that there is a Mayer-Vietoris sequence in singular homology for any couple $\{X_1, X_2\}$ of subsets of X . However, for certain couples $\{X_1, X_2\}$, there is a Mayer-Vietoris exact sequence of $\{X_1, X_2\}$: $\dots \xrightarrow{\partial_q} H_q(X_1 \cap X_2) \xrightarrow{\alpha} H_q(X_1) + H_q(X_2) \xrightarrow{\beta} H_q(X_1 \cup X_2) \xrightarrow{\partial_{q-1}^*} H_{q-1}(X_1 \cap X_2) \xrightarrow{\alpha} \dots$. For example, this holds if $X = \text{Int } X_1 \cup \text{Int } X_2$, where Int denotes the \dagger interior.

Let $c: X \rightarrow pt$ be the mapping of a topological space to a single point. Then the kernel of $c_*: H_*(X) \rightarrow H_*(pt)$ is denoted by $\tilde{H}_*(X)$ and is called the **reduced homology group** of X . It holds that $H_*(X) \cong \tilde{H}_*(X) + H_*(pt)$. Regard the \dagger suspension SX as the union of two copies of the \dagger cone over X . Then the connecting homomorphism in the Meyer-Vietoris sequence gives an isomorphism $\tilde{H}_q(SX) \cong \tilde{H}_{q-1}(X)$ for any q . The inverse of this isomorphism is called the **suspension isomorphism for homology**.

Let M be a $\dagger C^\infty$ -manifold. A C^∞ -singular q -simplex in M is a singular q -simplex $\sigma: \Delta^q \rightarrow M$ such that σ extends to a C^∞ -mapping from an open neighborhood of Δ^q in $\{(t_0, t_1, \dots, t_q) \in \mathbb{R}^{q+1} \mid t_0 + t_1 + \dots + t_q = 1\}$ to M . The totality of C^∞ -singular simplexes in M generates a subcomplex of $S(M)$, denoted by $S^\infty(M)$. The inclusion $S^\infty(M) \subset S(M)$ induces an isomorphism $H_*(S^\infty(M)) \cong H_*(M)$.

Let M be an n -dimensional \dagger topological manifold. Then $H_q(M) = 0$ unless $0 \leq q \leq n$, and $H_*(M)$ is finitely generated if M is compact.

F. Homology of CW Complexes

Homology theory is tractable in the category of \dagger CW complexes by virtue of the facts stated below.

Let X be a topological space and A its subset. Then we denote by X/A the quotient space obtained from X by shrinking A to a point, understanding X/\emptyset to be the disjoint union $X \cup pt$. If X_1, X_2 are \dagger subcomplexes of a CW complex, then the Mayer-Vietoris exact sequence of $\{X_1, X_2\}$ and the **excision isomorphism** $i_*: H_*(X_1/(X_1 \cap X_2)) \cong H_*((X_1 \cup X_2)/X_2)$ (i : inclusion) are valid. If A is a subcomplex of a CW complex X , then we have the following **reduced homology exact sequence** of $(X, A): \dots \xrightarrow{\partial_*} \tilde{H}_q(X) \xrightarrow{i_*} \tilde{H}_q(X/A) \xrightarrow{j_*} \tilde{H}_{q-1}(A) \xrightarrow{i_*} \dots$, where i_* and j_* are induced by the inclusion $i: A \rightarrow X$ and the collapsing $j: X \rightarrow X/A$, and ∂_* is given by a commutative diagram

$$\begin{array}{ccccc} \tilde{H}_q(X/A) & \xrightarrow{\partial_*} & \tilde{H}_{q-1}(A) \\ \cong \uparrow h_* & & \cong \downarrow S \\ \tilde{H}_q(X \cup CA) & \xrightarrow{h_*} & \tilde{H}_q(SA) \end{array}$$

Here CA is the cone over A , S is the suspension isomorphism, and $h: X \cup CA \rightarrow (X \cup CA)/CA = X/A$ and $h': X \cup CA \rightarrow (X \cup CA)/X = SA$ are collapsings. More generally, if A, B are subcomplexes of a CW complex X and $A \supset B$, then we have the following **reduced homology exact sequence** of $(X, A, B): \dots \xrightarrow{\partial_*} \tilde{H}_q(A/B) \xrightarrow{i_*} \tilde{H}_q(X/B) \xrightarrow{j_*} \tilde{H}_q(X/A) \xrightarrow{k_*} \tilde{H}_{q-1}(A/B) \xrightarrow{i_*} \dots$. Furthermore, the homology group $H_*(X)$ of a CW complex X can be computed in the following manner.

Let X^q denote the q -skeleton of X , i.e., the union of all cells of dimensions $\leq q$. Put $C_q(X) = \tilde{H}_q(X^q/X^{q-1})$, and let $\partial_q: C_q(X) \rightarrow C_{q-1}(X)$ be the connecting homomorphism $\partial_*: \tilde{H}_q(X^q/X^{q-1}) \rightarrow \tilde{H}_{q-1}(X^{q-1}/X^{q-2})$ in the reduced homology exact sequence of (X^q, X^{q-1}, X^{q-2}) . Then $C(X) = \{C_q(X), \partial_q\}$ is a chain complex such that $C_q(X)$ is a free Abelian group with one generator for each q -cell of X . If X is a polyhedron $|K|$, then $C(X)$ coincides with the simplicial chain complex $C(K)$. The homology group $H_*(C(K))$ is called the **cellular homology group** of the CW complex X . This is isomorphic to the singular homology group $H_*(X)$.

Since a CW decomposition frequently requires fewer cells than a simplicial decomposition, the cellular homology groups are useful in calculating the homology groups. For example, the \dagger complex n -dimensional projective space CP^n has a CW decomposition with a single $2i$ -cell for each $i = 0, 1, \dots, n$, and hence we see immediately that $H_q(CP^n) \cong \mathbb{Z}$ if $q = 2i$ ($0 \leq i \leq n$) and $= 0$ otherwise.

If X is a finite CW complex and α_q denotes

the number of q -cells of X , then we have the **Euler-Poincaré formula** $\chi(X) = \sum_q (-1)^q \alpha_q$. In particular, if X is homeomorphic to S^2 then we have the **Euler theorem on polyhedra**: $\alpha_0 - \alpha_1 + \alpha_2 = 2$. This was the first important result in topology (L. Euler, 1752).

G. Homology with Coefficients in Abelian Groups

Given a chain complex C and an Abelian group G , we have a new chain complex $C \otimes G$ given by $(C \otimes G)_q = C_q \otimes G$ and $\partial_q(c \otimes g) = \partial_q c \otimes g$ ($c \in C_q, g \in G$), where \otimes is the \dagger tensor product of Abelian groups. For a topological space X , the homology group of the chain complex $S(X) \otimes G$ is denoted by $H_*(X; G)$ and is called the **singular homology group of X with coefficients in G** . The **homology group $H_*(K; G)$ of a simplicial complex K with coefficients in G** and the **cellular homology group $H_*(C(X); G)$ of a CW complex X with coefficients in G** are similarly defined. The homology group with coefficients in \mathbb{Z} is the integral homology group.

The previous results for the integral homology groups generalize in a straightforward fashion to homology groups with coefficients in G .

We have the homomorphism $\kappa: H_q(X) \otimes G \rightarrow H_q(X; G)$ sending $a \otimes g \in H_q(X) \otimes G$ to the homology class of $z \otimes g \in Z_q(S(X) \otimes G)$, where z is a representative cycle of a . The following theorem is known as the **universal coefficient theorem for homology**, since it expresses $H_q(X; G)$ in terms of $H_q(X)$, $H_{q-1}(X)$, and G : There is an exact sequence $0 \rightarrow H_q(X) \otimes G \xrightarrow{\kappa} H_q(X; G) \rightarrow \text{Tor}(H_{q-1}(X), G) \rightarrow 0$, and this sequence is split (\rightarrow 200 Homological Algebra). Universal coefficient theorems of this type were first shown by S. Eilenberg and S. MacLane (*Ann. Math.*, (2) 43 (1942)).

Let Λ be a \dagger ring with a unit 1. Then a **chain complex over Λ** is a chain complex C such that each C_q is a $\dagger\Lambda$ -module and each ∂_q is a $\dagger\Lambda$ -homomorphism. The homology groups $H_q(C)$ of a chain complex C over Λ are Λ -modules. If C is a chain complex, $C \otimes \Lambda$ forms naturally a chain complex over Λ . In particular, if X is a topological space, then $S(X) \otimes \Lambda$ is a chain complex over Λ , and $H_q(X; \Lambda)$ are Λ -modules. In this case, the induced homomorphisms $f_*: H_q(X; \Lambda) \rightarrow H_q(Y; \Lambda)$ are Λ -homomorphisms. The homology groups with coefficients in a field \mathbf{k} are \dagger vector spaces over \mathbf{k} and are useful in applications. If $H_*(X)$ is finitely generated, then $\chi(X) = \sum_q (-1)^q \dim_{\mathbf{k}} H_q(X; \mathbf{k})$ holds for any field \mathbf{k} .

H. Cohomology

A **cochain complex** $C = \{C^q, \delta^q\}$ is a collection of Abelian groups C^q , one for each integer q , and of homomorphisms $\delta^q: C^q \rightarrow C^{q+1}$ such that $\delta^{q+1} \circ \delta^q = 0$. Elements of C^q are called q -**cochains**, and δ^q is called the **coboundary operator**. The notions of **subcomplex of a cochain complex**, **cocycle**, **coboundary**, **cohomology group**, and **cochain mapping** are defined as in chain complex. Let $\text{Hom}(A, B)$ denote the \dagger group of homomorphisms from an Abelian group A to an Abelian group B . Given a chain complex C and an Abelian group G , a cochain complex $C^* = \text{Hom}(C, G)$ is defined by $C^q = \text{Hom}(C_q, G)$ and $(\delta^q u)(c) = u(\partial_{q+1} c)$ ($u \in C^q, c \in C_{q+1}$).

For a topological space X , the cochain complex $\text{Hom}(S(X), G)$ is called the **singular cochain complex** of X with coefficients in G , and elements of $\text{Hom}(S_q(X), G)$ are called **singular q -cochains** of X . The cohomology group of $\text{Hom}(S(X), G)$ is denoted by $H^*(X; G)$ and is called the **singular cohomology group of X with coefficients in G** . We write $H^*(X)$ for $H^*(X; \mathbf{Z})$; this is called the **integral cohomology group of X** . Similarly, the **cohomology group $H^*(K; G)$ of a simplicial complex K with coefficients in G** and the **cellular cohomology group $H^*(C(X); G)$ of a CW complex X with coefficients in G** are defined. There are isomorphisms $H^*(K; G) \cong H^*(|K|; G)$ and $H^*(C(X); G) \cong H^*(X; G)$.

If $f: X \rightarrow Y$ is a continuous mapping, then a cochain map $f^*: \text{Hom}(S(Y), G) \rightarrow \text{Hom}(S(X), G)$ is defined by $(f^* u)(c) = u(f_\# c)$ with $u \in \text{Hom}(S_q(Y), G)$ and $c \in S_q(X)$. Therefore f induces the homomorphism $f^*: H^*(Y; G) \rightarrow H^*(X; G)$. The following properties hold: (i) $1^* = 1$; (ii) $(g \circ f)^* = f^* \circ g^*$; (iii) If f and f' are homotopic, then $f^* = f'^*$. In particular, the singular cohomology groups are homotopy invariants. The 'cokernel of $c^*: H^*(pt; G) \rightarrow H^*(X; G)$ induced by the mapping $c: X \rightarrow pt$ is denoted by $\tilde{H}^*(X; G)$ and is called the **reduced cohomology group of X** .

For $\xi \in H^q(X; G)$ and $a \in H_q(X)$, the **Kronecker index** $\langle \xi, a \rangle \in G$ is defined naturally in terms of representatives of ξ and a . We have the following **universal coefficient theorem for cohomology**: There is an exact sequence $0 \rightarrow \text{Ext}(H_{q-1}(X), G) \rightarrow H^q(X; G) \xrightarrow{\kappa} \text{Hom}(H_q(X), G) \rightarrow 0$, and this sequence is split, where κ is given by the Kronecker index (\rightarrow 200 Homological Algebra).

If Λ is a ring with 1, then a **cochain complex over Λ** is defined analogously to a chain complex over Λ . The singular cochain complex $\text{Hom}(S(X), \Lambda)$ forms naturally a cochain complex over Λ , and $H^q(X; \Lambda)$ are Λ -modules. For $\xi \in H^q(X; \Lambda)$ and $a \in H_q(X; \Lambda)$, the **Kronecker**

index $\langle \xi, a \rangle \in \Lambda$ is defined naturally. If \mathbf{k} is a field, then the vector spaces $H^q(X; \mathbf{k})$ are identified with the dual space of $H_q(X, \mathbf{k})$ by means of the Kronecker index.

If M is a C^∞ -manifold, then there is a cochain complex $\mathfrak{D}(M) = \{\mathfrak{D}^q(M), d\}$ over the field \mathbf{R} of real numbers, where $\mathfrak{D}^q(M)$ is the real vector space consisting of the \dagger differential forms of degree q on M , and $d: \mathfrak{D}^q(M) \rightarrow \mathfrak{D}^{q+1}(M)$ is the \dagger exterior differentiation. The cochain complex $\mathfrak{D}(M)$ is called the **de Rham complex** of M , and its cohomology group $H^*(\mathfrak{D}(M))$ is called the **de Rham cohomology group of M** . A cochain mapping $\mathcal{J}: \mathfrak{D}(M) \rightarrow \text{Hom}(S^\infty(M), \mathbf{R})$ is defined by

$$(\mathcal{J}(\omega))(\sigma) = \int_{\Delta^q} \sigma^* \omega,$$

where $\omega \in \mathfrak{D}^q(M)$, $\sigma: \Delta^q \rightarrow M$ is a C^∞ singular q -simplex in M , and $\sigma^* \omega$ denotes the \dagger pullback of ω by σ . We have isomorphisms

$$H^*(\mathfrak{D}(M)) \xrightarrow{\mathcal{J}} H^*(\text{Hom}(S^\infty(M), \mathbf{R})) \xleftarrow{i^*} H^*(M; \mathbf{R}),$$

where i^* is induced by the inclusion $S^\infty(M) \subset S(M)$. This result is called the **de Rham theorem** on the cohomology of manifolds (\rightarrow 105 Differentiable Manifolds).

I. Cohomology Rings

Given a topological space X and a ring Λ , the **cup product** $u \smile v \in \text{Hom}(S_{p+q}(X), \Lambda)$ of cochains $u \in \text{Hom}(S_p(X), \Lambda)$ and $v \in \text{Hom}(S_q(X), \Lambda)$ is defined by $(u \smile v)(\sigma) = u(\sigma \circ \varepsilon)v(\sigma \circ \varepsilon')$, where $\sigma: \Delta^{p+q} \rightarrow X$ is a singular $(p+q)$ -simplex, $\varepsilon: \Delta^p \rightarrow \Delta^{p+q}$ and $\varepsilon': \Delta^q \rightarrow \Delta^{p+q}$ are given by $\varepsilon(t_0, t_1, \dots, t_p) = (t_0, t_1, \dots, t_p, 0, \dots, 0)$, and $\varepsilon'(t_p, t_{p+1}, \dots, t_{p+q}) = (0, \dots, 0, t_p, t_{p+1}, \dots, t_{p+q})$. The product operation is bilinear, and the formula $\delta(u \smile v) = \delta u \smile v + (-1)^p u \smile \delta v$ holds. Therefore it gives rise to the **cup product** $\xi \smile \eta \in H^{p+q}(X; \Lambda)$ of cohomology classes $\xi \in H^p(X; \Lambda)$ and $\eta \in H^q(X; \Lambda)$. This cup product operation makes $H^*(X; \Lambda)$ into a ring, which is called the **singular cohomology ring** of X with coefficients in Λ . If Λ has 1, the cohomology class represented by the 0-cocycle taking the value 1 on each singular 0-simplex serves as 1 of $H^*(X; \Lambda)$. If Λ is commutative, then $\xi \eta = (-1)^{pq} \eta \xi$ holds. The induced homomorphism $f^*: H^*(Y; \Lambda) \rightarrow H^*(X; \Lambda)$ preserves the product, and hence the cohomology ring is a homotopy invariant.

If K is a simplicial complex, the **cup product** operation $\smile: H^p(K; \Lambda) \otimes H^q(K; \Lambda) \rightarrow H^{p+q}(K; \Lambda)$ is induced from the operation $\smile: \text{Hom}(C_p(K), \Lambda) \otimes \text{Hom}(C_q(K), \Lambda) \rightarrow \text{Hom}(C_{p+q}(K), \Lambda)$ defined as follows. Adopting a \dagger linear ordering of vertices of K , we write all oriented simplexes in this ordering. Then,

for $u \in \text{Hom}(C_p(K), \Lambda)$ and $v \in \text{Hom}(C_q(K), \Lambda)$, we define $u \smile v \in \text{Hom}(C_{p+q}(K), \Lambda)$ by $(u \smile v)([a_0, a_1, \dots, a_{p+q}]) = u([a_0, a_1, \dots, a_p])v([a_{p+1}, \dots, a_{p+q}])$. The canonical isomorphism from the cohomology of K to the singular cohomology of $|K|$ preserves the cup product.

On the de Rham complex $\mathfrak{D}(M)$ of a C^∞ -manifold M , we have the exterior product $\omega \wedge \theta \in \mathfrak{D}^{p+q}(M)$ of $\omega \in \mathfrak{D}^p(M)$ and $\theta \in \mathfrak{D}^q(M)$. This makes $H^*(\mathfrak{D}(M))$ into a ring, which is called the **de Rham cohomology ring**. The canonical isomorphism of $H^*(\mathfrak{D}(M))$ to $H^*(M; \mathbb{R})$ preserves the product (\rightarrow 105 Differentiable Manifolds).

Examples. (1) Let $T^n = S^1 \times \dots \times S^1$ denote the n -dimensional torus, and let $\pi_i: T^n \rightarrow S^1$ denote the projection to the i th factor ($1 \leq i \leq n$). Take a generator ξ of the Λ -module $H^1(S^1; \Lambda)$, and put $\xi_i = \pi_i^*(\xi) \in H^1(T^n; \Lambda)$. Then $H^*(T^n; \Lambda)$ is the exterior algebra over Λ generated by ξ_1, \dots, ξ_n . (2) If we denote by CP^n the complex n -dimensional projective space, then $H^q(CP^n; \Lambda)$ is Λ if $q = 2i$ ($0 \leq i \leq n$) and 0 otherwise. If ξ is a generator of the Λ -module $H^2(CP^n; \Lambda)$, then ξ^i generates the Λ -module $H^{2i}(CP^n; \Lambda)$ ($0 \leq i \leq n$). Thus $H^*(CP^n; \Lambda)$ is the quotient ring $\Lambda[\xi]/(\xi^{n+1})$ of the polynomial ring $\Lambda[\xi]$ by the ideal (ξ^{n+1}) . (3) If P^n denote the real n -dimensional projective space, then $H^*(P^n; \mathbb{Z}_2) \cong \mathbb{Z}_2[\xi]/(\xi^{n+1})$, where ξ is the generator of $H^1(P^n; \mathbb{Z}_2)$.

J. Homology of Product Spaces

If C and D are chain complexes, their **tensor product** $C \otimes D$ is a chain complex given by $(C \otimes D)_n = \sum_{p+q=n} C_p \otimes D_q$, and $\partial_n(c \otimes d) = \partial_p(c) \otimes d + (-1)^p c \otimes \partial_q(d)$ ($c \in C_p, d \in D_q$). The following **Eilenberg-Zilber theorem** (*Amer. J. Math.*, 75 (1953)) is the link between the algebra of tensor products and the geometry of product spaces: For the product space $X \times Y$ of topological spaces X and Y , there is an isomorphism $\rho_*: H_*(X \times Y; \mathbb{G}) \cong H_*(S(X) \otimes S(Y) \otimes \mathbb{G})$ induced from a chain mapping $\rho: S(X \times Y) \rightarrow S(X) \otimes S(Y)$ defined as follows: Given a singular n -simplex $\sigma: \Delta^n \rightarrow X \times Y$, we define for each p ($0 \leq p \leq n$) a singular p -simplex σ'_p in X to be the composite $\Delta^p \xrightarrow{\pi_1} \Delta^n \xrightarrow{\sigma} X \times Y \xrightarrow{\pi_1} X$, where $\varepsilon(t_0, t_1, \dots, t_p) = (t_0, t_1, \dots, t_p, 0, \dots, 0)$ and π_1 is the projection to the first factor. Similarly, we define for each q ($0 \leq q \leq n$) a singular q -simplex σ''_q in Y to be the composite $\Delta^q \xrightarrow{\pi_2} \Delta^n \xrightarrow{\sigma} X \times Y \xrightarrow{\pi_2} Y$, where $\varepsilon'(t_{n-q}, \dots, t_n) = (0, \dots, 0, t_{n-q}, \dots, t_n)$ and π_2 is the projection to the second factor. Then ρ is defined by $\rho(\sigma) = \sum_{p+q=n} \sigma'_p \otimes \sigma''_q$ and is called the **Alexander-Whitney mapping** (**Alexander-Whitney map**).

Given a ring Λ , a chain mapping $\mu: (S(X) \otimes$

$S(Y) \otimes \Lambda) \rightarrow S(X) \otimes S(Y) \otimes \Lambda$ is defined by $\mu((c \otimes \lambda') \otimes (d \otimes \lambda'')) = c \otimes d \otimes \lambda' \lambda''$; it induces homomorphisms $\mu_*: H_p(X; \Lambda) \otimes H_q(Y; \Lambda) \rightarrow H_{p+q}(S(X) \otimes S(Y) \otimes \Lambda)$. The **cross product** $a \times b \in H_{p+q}(X \times Y; \Lambda)$ of $a \in H_p(X; \Lambda)$ and $b \in H_q(Y; \Lambda)$ is defined to be $\rho_*^{-1}(\mu_*(a \otimes b))$. If Λ is a commutative ring with 1, then the cross product defines a Λ -homomorphism $\times: H_p(X; \Lambda) \otimes_\Lambda H_q(Y; \Lambda) \rightarrow H_{p+q}(X \times Y; \Lambda)$, and satisfies $(a \times b) \times c = a \times (b \times c)$, $T_*(a \times b) = (-1)^{pq} b \times a$, $(f \times g)_*(a \times b) = f_*(a) \times g_*(b)$, where $T: X \times Y \rightarrow Y \times X$ is the mapping interchanging factors, and $f: X \rightarrow X'$, $g: Y \rightarrow Y'$ are continuous mappings. If Λ is a principal ideal domain, there is an exact sequence

$$0 \rightarrow \sum_{p+q=n} H_p(X; \Lambda) \otimes_\Lambda H_q(Y; \Lambda) \xrightarrow{\times} H_n(X \times Y; \Lambda) \rightarrow \sum_{p+q=n-1} \text{Tor}_\Lambda(H_p(X; \Lambda), H_q(Y; \Lambda)) \rightarrow 0,$$

and this sequence is split (\rightarrow 200 Homological Algebra). In particular, if \mathbf{k} is a field we have the following isomorphism of vector spaces:

$$\times: \sum_{p+q=n} H_p(X; \mathbf{k}) \otimes_{\mathbf{k}} H_q(Y; \mathbf{k}) \cong H_n(X \times Y; \mathbf{k}).$$

This is called the **Künneth theorem**, since the prototype was proved by D. Künneth (*Math. Ann.*, 90 (1923); *ibid.*, 91 (1924)). The present form was given by H. Cartan and S. Eilenberg [8].

The **tensor product** $C \otimes D$ of cochain complexes C and D is defined analogously to that of chain complexes. Given topological spaces X, Y and a ring Λ , a cochain mapping $\mu: \text{Hom}(S(X), \Lambda) \otimes \text{Hom}(S(Y), \Lambda) \rightarrow \text{Hom}(S(X) \otimes S(Y), \Lambda)$ is defined by $(\mu(u \otimes v))(c \otimes d) = u(c)v(d)$, where $u \in \text{Hom}(S_p(X), \Lambda)$, $v \in \text{Hom}(S_q(Y), \Lambda)$, $c \in S_p(X)$, $d \in S_q(Y)$, and $u(c)v(d)$ is understood to be 0 if $(p, q) \neq (s, t)$. We then have the composite $H^p(X; \Lambda) \otimes H^q(Y; \Lambda) \xrightarrow{\mu^*} H^{p+q}(\text{Hom}(S(X) \otimes S(Y), \Lambda)) \xrightarrow{\rho^*} H^{p+q}(X \times Y; \Lambda)$, where ρ is the Alexander-Whitney mapping. For $\xi \in H^p(X; \Lambda)$ and $\eta \in H^q(Y; \Lambda)$, the **cross product** $\xi \times \eta \in H^{p+q}(X \times Y; \Lambda)$ is defined to be $\rho^* \mu_*(\xi \otimes \eta)$. The cohomology cross product satisfies the properties analogous to the homology cross product.

The cup product and the cohomology cross product are given in terms of each other: $\xi \smile \eta = d^*(\xi \times \eta)$, $\xi \times \eta = \pi_1^*(\xi) \smile \pi_2^*(\eta)$, where $d: X \rightarrow X \times X$ is given by $d(x) = (x, x)$, and $\pi_1: X \times Y \rightarrow X$, $\pi_2: X \times Y \rightarrow Y$ are projections.

We have the following **Künneth theorem** for cohomology: If Λ is a principal ideal domain and each $H_q(X; \Lambda)$ is finitely generated over Λ , then there is an exact sequence

$$0 \rightarrow \sum_{p+q=n} H^p(X; \Lambda) \otimes_\Lambda H^q(Y; \Lambda) \xrightarrow{\times} H^n(X \times Y; \Lambda) \rightarrow \sum_{p+q=n+1} \text{Tor}_\Lambda(H^p(X; \Lambda), H^q(Y; \Lambda)) \rightarrow 0,$$

and this sequence is split (\rightarrow 200 Homological Algebra). For $\xi \in H^p(X; \Lambda)$, $\eta \in H^q(Y; \Lambda)$, $\xi' \in H^s(X; \Lambda)$, $\eta' \in H^t(Y; \Lambda)$, the formula $(\xi \times \eta) \smile (\xi' \times \eta') = (-1)^{qs}(\xi \smile \xi') \times (\eta \smile \eta')$ holds. Therefore, if k is a field and $\dim_k H_q(X; k) < \infty$ for each q , then the cohomology ring $H^*(X \times Y; k)$ is determined by the cohomology rings $H^*(X; k)$ and $H^*(Y; k)$.

†Fiber bundles can be considered as generalized product spaces. Let E be the total space of a fiber bundle with base B and fiber F . The following **Leray-Hirsch theorem** (*J. Math. Pures Appl.*, 29 (1950)) asserts that, under certain conditions, the cohomology of E is additively isomorphic to that of $B \times F$: Let Λ be a principal ideal domain, and assume that $H_*(F; \Lambda)$ is free and finitely generated over Λ . Furthermore, assume that there is a homomorphism $\theta: H^*(F; \Lambda) \rightarrow H^*(E; \Lambda)$ such that the composite $H^*(F; \Lambda) \xrightarrow{\theta} H^*(E; \Lambda) \xrightarrow{i_b^*} H^*(p^{-1}(b); \Lambda)$ is an isomorphism for each $b \in B$, where $p: E \rightarrow B$ is the projection and $i_b: p^{-1}(b) \subset E$. Then an isomorphism $\Phi: H^*(B; \Lambda) \otimes_\Lambda H^*(F; \Lambda) \cong H^*(E; \Lambda)$ is given by $\Phi(\xi \otimes \eta) = p^* \xi \smile \theta(\eta)$, where $\xi \in H^*(B; \Lambda)$, $\eta \in H^*(F; \Lambda)$.

A general connection between (co)homology of E and $B \times F$ is given by means of spectral sequences (\rightarrow 148 Fiber Spaces).

K. Cap and Slant Products

There are other products closely related to the cup product or the cross product that involve cohomology and homology together.

Given a topological space X and a ring Λ , the **cap product** $v \frown c \in S_p(X) \otimes \Lambda$ of a **cochain** $v \in \text{Hom}(S_q(X), \Lambda)$ and a **chain** $c = \sum_i \sigma_i \otimes \lambda_i \in S_{p+q}(X) \otimes \Lambda$ is defined by $v \frown c = \sum_i \sigma_i \circ \varepsilon \otimes v(\sigma_i \circ \varepsilon') \lambda_i$, where σ_i are singular $(p+q)$ -simplexes in X , $\lambda_i \in \Lambda$, and $\varepsilon: \Delta^p \rightarrow \Delta^{p+q}$, $\varepsilon': \Delta^q \rightarrow \Delta^{p+q}$ are the mappings used in the definition of cup product. For any $u \in \text{Hom}(S_p(X), \Lambda)$, the formula $\langle u \smile v, c \rangle = \langle u, v \frown c \rangle$ holds. The cap product satisfies $\partial(v \frown c) = (-1)^p \partial v \frown c + v \frown \partial c$, and hence it induces the **cap product** $\xi \frown a \in H_p(X; \Lambda)$ of a **cohomology class** $\xi \in H^q(X; \Lambda)$ and a **homology class** $a \in H_{p+q}(X; \Lambda)$. If Λ is a commutative ring with 1, then the cap product operation is bilinear and satisfies the following properties: $(\xi \smile \xi') \frown a = \xi \frown (\xi' \frown a)$, $f_*(f^* \eta \frown a) = \eta \frown f_*(a)$, $1 \frown a = a$, $(\xi \times \eta) \frown (a \times b) = (-1)^{p(q-t)} (\xi \frown a) \times (\eta \frown b)$, where $\xi \in H^p(X; \Lambda)$, $\xi' \in H^p(X; \Lambda)$, $\eta \in H^q(Y; \Lambda)$, $a \in H_s(X; \Lambda)$, $b \in H_t(Y; \Lambda)$, and $f: X \rightarrow Y$ is a continuous mapping.

Given topological spaces X , Y and a ring Λ , the **slant product** $w/d \in \text{Hom}(S_p(X), \Lambda)$ of a **cochain** $w \in \text{Hom}(S(X) \otimes S(Y), \Lambda)$ and a **chain** $d = \sum_i \tau_i \otimes \lambda_i \in S_q(Y) \otimes \Lambda$ is defined

by $(w/d)(\sigma) = \sum_i (w(\sigma \otimes \tau_i)) \lambda_i$, where σ is a singular p -simplex in X , τ_i are singular q -simplexes in Y , and $\lambda_i \in \Lambda$. The slant operation satisfies $\delta(w/d) = (\delta w)/d - (-1)^p w/\partial d$. Therefore, under the identification $H^*(X \times Y; \Lambda) = H^*(\text{Hom}(S(X) \otimes S(Y), \Lambda))$, it induces the **slant product** $\zeta/b \in H^p(X; \Lambda)$ of a **cohomology class** $\zeta \in H^{p+q}(X \times Y; \Lambda)$ and a **homology class** $b \in H_q(Y; \Lambda)$. For any $a \in H_p(X; \Lambda)$, it holds that $\langle \zeta/b, a \rangle = \langle \zeta, a \times b \rangle$.

Let G , G' and G'' be Abelian groups. Given a homomorphism $G' \otimes G'' \rightarrow G$, we write $g'g''$ for the image of $g' \otimes g'' \in G' \otimes G''$ in G . Then the cap product $\frown: H^q(X; G') \otimes H_{p+q}(X; G'') \rightarrow H_p(X; G)$ can be defined in the same way as before. Similar definitions are valid for the cup product, the cross products for homology and cohomology, and the slant product.

L. Relative Homology

If C' is a subcomplex of a chain complex C , then we have a chain complex $C/C' = \{C_q/C'_q, \bar{\partial}_q\}$, where C_q/C'_q denotes the quotient group and $\bar{\partial}_q$ is induced from ∂_q by passing to the quotient. C/C' is called the **quotient complex** of C by C' .

A **topological pair** (X, A) is composed of a topological space X and its subset A . Given a topological pair (X, A) and an Abelian group G , we have the chain complex $(S(X)/S(A)) \otimes G$ and the cochain complex $\text{Hom}(S(X)/S(A), G)$. The homology group of $(S(X)/S(A)) \otimes G$ is denoted by $H_*(X, A; G)$ and is called the **relative singular homology group of X modulo A with coefficients in G** or the **singular homology group of (X, A) with coefficients in G** . The homology group $H_*(X; G) = H_*(X, \emptyset; G)$ is sometimes called the **absolute homology group**. Similar definitions are made for the cohomology group $H^*(X, A; G)$ of the cochain complex $\text{Hom}(S(X)/S(A), G)$.

A **simplicial pair** (K, L) is composed of a simplicial complex K and its subcomplex L , and a **CW pair** (X, A) is composed of a CW complex X and its subcomplex A . The relative homology group $H_*(K, L; G) = H_*((C(K)/C(L)) \otimes G)$ of a simplicial pair (K, L) is isomorphic to $H_*(|K|, |L|; G)$. For a CW pair (X, A) , there is an isomorphism $H_*(X, A; G) \cong \tilde{H}_*(X/A; G)$. Similar statements hold for the cohomology groups.

A continuous mapping $f: (X, A) \rightarrow (Y, B)$ of topological pairs is a continuous mapping $f: X \rightarrow Y$ such that $f(A) \subset B$. If $f: (X, A) \rightarrow (Y, B)$ is a continuous mapping, then $f_\#: S(X) \rightarrow S(Y)$ sends $S(A)$ to $S(B)$, and hence f induces homomorphisms $f_*: H_*(X, A; G) \rightarrow H_*(Y, B; G)$ and

$f^*: H^*(Y, B; G) \rightarrow H^*(X, A; G)$. Since the properties are analogous, we state them below only for the case of relative homology.

The following six properties are fundamental. (i) $1_* = 1$. (ii) $(g \circ f)_* = g_* \circ f_*$. (iii) Homotopy property: If $f, f': (X, A) \rightarrow (Y, B)$ are \dagger homotopic, then $f_* = f'_*$. (iv) Exactness property: There exists a **homology exact sequence of** $(X, A): \dots \xrightarrow{\partial_*} H_q(A; G) \xrightarrow{i_*} H_q(X; G) \xrightarrow{j_*} H_q(X, A; G) \xrightarrow{\partial_*} H_{q-1}(A; G) \xrightarrow{i_*} \dots$, where $i: A \subset X, j: (X, \emptyset) \subset (X, A)$, and ∂_* sends the homology class of a cycle of $(S(X)/S(A)) \otimes G$ represented by a chain $c \in S(X) \otimes G$ to the homology class of ∂c which is a cycle of $S(A) \otimes G$. ∂_* is called the **boundary homomorphism** or the **connecting homomorphism**. (v) Naturality of ∂_* : For any continuous mapping $f: (X, A) \rightarrow (Y, B)$, it holds that $\partial_* \circ f_* = (f|_A)_* \circ \partial_*$. (vi) Excision property: If U is a subset of X such that the closure \bar{U} is in $\text{Int } A$, then the **excision isomorphism** $H_*(X - U, A - U; G) \cong H_*(X, A; G)$ is induced by inclusion.

The exactness property extends to the **homology exact sequence of a triple** (X, A, B) : $\dots \xrightarrow{\partial_*} H_q(A, B; G) \xrightarrow{i_*} H_q(X, B; G) \xrightarrow{j_*} H_q(X, A; G) \xrightarrow{\partial_*} H_{q-1}(A, B; G) \xrightarrow{i_*} \dots$. A couple $\{X_1, X_2\}$ of subsets of X is said to be **excisive** if $H_*(X_1, X_1 \cap X_2) \cong H_*(X_1 \cup X_2, X_2)$ is induced by inclusion. If $\{X_1, X_2\}$ is excisive, so is $\{X_2, X_1\}$. For example, if $X = \text{Int } X_1 \cup \text{Int } X_2$ or if X_1 and X_2 are subcomplexes of a CW complex, then $\{X_1, X_2\}$ is excisive. If $\{X_1, X_2\}$ and $\{A_1, A_2\}$ are excisive couples such that $A_1 \subset X_1$ and $A_2 \subset X_2$, then we have the **relative Mayer-Vietoris exact sequence**: $\dots \rightarrow H_q(X_1 \cap X_2, A_1 \cap A_2; G) \rightarrow H_q(X_1, A_1; G) + H_q(X_2, A_2; G) \rightarrow H_q(X_1 \cup X_2, A_1 \cup A_2; G) \rightarrow H_{q-1}(X_1 \cap X_2, A_1 \cap A_2; G) \rightarrow \dots$. For the case of relative cohomology, we use terms such as **cohomology exact sequence** and **coboundary homomorphism**, correspondingly.

The universal coefficient theorems are valid for the relative (co)homology groups. Given a homomorphism $G' \otimes G'' \rightarrow G$, if $\{A, B\}$ is excisive in X , then the cup product $\smile: H^p(X, A; G') \otimes H^q(X, B; G'') \rightarrow H^{p+q}(X, A \cup B; G)$ and the cap products $\frown: H^q(X, B; G') \otimes H_{p+q}(X, A \cup B; G'') \rightarrow H_p(X, A; G)$ can be defined. The product $(X, A) \times (Y, B)$ is defined to be the pair $(X \times Y, A \times Y \cup X \times B)$. Given a homomorphism $G' \otimes G'' \rightarrow G$, the homology cross products $\times: H_p(X, A; G') \otimes H_q(Y, B; G'') \rightarrow H_{p+q}((X, A) \times (Y, B); G)$ and the slant products $/: H^{p+q}((X, A) \times (Y, B); G') \otimes H_q(Y, B; G'') \rightarrow H^p(X, A; G)$ can be defined. If $\{A \times Y, X \times B\}$ is excisive, then the cohomology cross products $\times: H^p(X, A; G') \otimes H^q(Y, B; G'') \rightarrow H^{p+q}((X, A) \times (Y, B); G)$ can also be defined. If $\{A \times Y, X \times B\}$ is excisive, the Künneth theorems are valid for the relative (co)homology groups [9, 10, 11].

M. Čech Homology Theory

Another homology theory is commonly used along with the singular theory. The theory was originated by E. Čech (*Fund. Math.*, 19 (1932)) and was modified by C. H. Dowker (*Ann. Math.*, (2) 51 (1950)).

Given a topological space X and an Abelian group G , the **Čech homology group** $\check{H}_*(X; G)$ and the **Čech cohomology group** $\check{H}^*(X; G)$ are defined as follows. We take the family of all \dagger open coverings of X directed by \dagger refinement, and we consider the \dagger nerve $K(\mathcal{U})$ of each open covering \mathcal{U} , that is, the simplicial complex whose simplexes are finite nonempty subsets of \mathcal{U} with nonempty intersection. If \mathcal{U}' is a refinement of \mathcal{U} , then a simplicial mapping $\pi(\mathcal{U}, \mathcal{U}'): K(\mathcal{U}') \rightarrow K(\mathcal{U})$ is obtained by assigning to each $U' \in \mathcal{U}'$ an element $U \in \mathcal{U}$ such that $U' \subset U$. The induced homomorphisms $\pi(\mathcal{U}, \mathcal{U}')_*: H_*(K(\mathcal{U}'); G) \rightarrow H_*(K(\mathcal{U}); G)$ and $\pi(\mathcal{U}, \mathcal{U}')^*: H^*(K(\mathcal{U}); G) \rightarrow H^*(K(\mathcal{U}'); G)$ are independent of the choice of $\pi(\mathcal{U}, \mathcal{U}')$, and we have the \dagger inverse system $\{H_*(K(\mathcal{U}); G), \pi(\mathcal{U}, \mathcal{U}')_*\}$ and the \dagger direct system $\{H^*(K(\mathcal{U}); G), \pi(\mathcal{U}, \mathcal{U}')^*\}$. We now define $\check{H}_*(X; G) = \varprojlim H_*(K(\mathcal{U}); G)$ and $\check{H}^*(X; G) = \varinjlim H^*(K(\mathcal{U}); G)$.

A continuous mapping $f: X \rightarrow Y$ induces homomorphisms $f_*: \check{H}_*(X; G) \rightarrow \check{H}_*(Y; G)$ and $f^*: \check{H}^*(Y; G) \rightarrow \check{H}^*(X; G)$ as follows. If \mathfrak{B} is an open covering of Y then a simplicial mapping $f_{\mathfrak{B}}: K(f^{-1}(\mathfrak{B})) \rightarrow K(\mathfrak{B})$ is defined by $f_{\mathfrak{B}}(f^{-1}(V)) = V$ ($V \in \mathfrak{B}$). The induced homomorphisms $f_{\mathfrak{B}*}: H_*(K(f^{-1}(\mathfrak{B})); G) \rightarrow H_*(K(\mathfrak{B}); G)$ for all open coverings \mathfrak{B} of Y gives rise to $f_*: \check{H}_*(X; G) \rightarrow \check{H}_*(Y; G)$. Similarly f induces f^* .

Another approach to Čech cohomology theory is called the Alexander-Kolmogorov construction (*Proc. Nat. Acad. Sci.*, 21 (1935) and *C. R. Acad. Sci. Paris*, 202 (1936)). The approach was improved by E. H. Spanier (*Ann. Math.*, (2) 49 (1948)), and the theory is now called the **Alexander- (or Alexander-Kolmogorov-Spanier) cohomology theory**.

The **Alexander cohomology group** $\bar{H}^*(X; G)$ is defined as follows. Let $\Phi^q(X; G)$ be the Abelian group of all functions from the $(q+1)$ -fold product space X^{q+1} to G with addition defined pointwise. An element $\varphi \in \Phi^q(X; G)$ is said to be locally zero if there is an open covering \mathcal{U} of X such that $\varphi(x_0, \dots, x_q)$ vanishes if x_0, \dots, x_q are contained simultaneously in some $U \in \mathcal{U}$. The subgroup of $\Phi^q(X; G)$ consisting of locally zero functions is denoted by $\Phi_0^q(X; G)$. We define a homomorphism $\delta^q: \Phi^q(X; G) \rightarrow \Phi^{q+1}(X; G)$ by $(\delta^q \varphi)(x_0, x_1, \dots, x_{q+1}) = \sum_{i=0}^{q+1} (-1)^i \varphi(x_0, \dots, x_{i-1}, x_{i+1}, \dots, x_{q+1})$. Then $\Phi(X; G) = \{\Phi^q(X; G), \delta^q\}$ is a cochain complex, and $\Phi_0(X; G) = \{\Phi_0^q(X; G), \delta^q\}$ is its subcomplex. We now define $\bar{H}^*(X; G)$ to be

the cohomology group of the quotient complex $\Phi(X; G) = \Phi(X; G)/\Phi_0(X; G)$.

If $f: X \rightarrow Y$ is a continuous mapping, then a cochain map $f^\#: \Phi(Y; G) \rightarrow \Phi(X; G)$ is defined by $(f^\# \varphi)(x_0, x_1, \dots, x_q) = \varphi(f(x_0), f(x_1), \dots, f(x_q))$, and it induces the homomorphism $f^*: \bar{H}^*(Y; G) \rightarrow \bar{H}^*(X; G)$. There is a natural isomorphism $\check{H}^*(X; G) \cong \bar{H}^*(X; G)$.

The (co)homology group of a simplicial complex K is isomorphic to the Čech (co)homology group of $|K|$. If X is a manifold or a CW complex, then its singular (co)homology group and its Čech (co)homology group are isomorphic. However, even for compact metric spaces X , the singular (co)homology group of X is not necessarily isomorphic with the Čech (co)homology group of X .

If $\{X_\lambda\}$ is an \dagger inverse system of compact Hausdorff spaces and $X = \lim X_\lambda$, then there are isomorphisms $\lim \check{H}_*(X_\lambda; G) \cong \check{H}_*(X; G)$ and $\lim \check{H}^*(X_\lambda; G) \cong \check{H}^*(X; G)$. This is called the **continuity property for Čech theory**. If A is any closed subset of a manifold M , then there is an isomorphism $\lim H^*(W; G) \cong \check{H}^*(A; G)$, where W varies over neighborhoods of A in M directed downward by inclusion. If the \dagger covering dimension of X is n , $\check{H}^q(X; G) = 0$ for $q > n$.

The cup product in the Čech cohomology is introduced simply by passing to the limit with cup products in simplicial complexes, and the cup product in the Alexander cohomology is induced from the operation $\smile: \Phi^p(X; G') \otimes \Phi^q(X; G'') \rightarrow \Phi^{p+q}(X; G)$ defined by $(\varphi \smile \psi)(x_0, x_1, \dots, x_{p+q}) = \varphi(x_0, x_1, \dots, x_p)\psi(x_p, x_{p+1}, \dots, x_{p+q})$.

The **relative Čech homology group** $\check{H}_*(X, A; G)$ and the **relative Čech cohomology group** $\check{H}^*(X, A; G)$ are defined as follows: An open covering of (X, A) is a pair $(\mathcal{U}, \mathcal{V})$ of an open covering \mathcal{U} of X and an open covering \mathcal{V} of A such that $\mathcal{V} \subset \mathcal{U}$. To such a pair $(\mathcal{U}, \mathcal{V})$ we assign a simplicial pair $(K(\mathcal{U}), K'(\mathcal{V}))$, where $K'(\mathcal{V})$ is the nerve of $\mathcal{V} \cap A = \{N \cap A \mid N \in \mathcal{V}\}$. Considering the family of all open coverings of (X, A) , we define now $\check{H}_*(X, A; G) = \lim H_*(K(\mathcal{U}), K'(\mathcal{V}); G)$ and $\check{H}^*(X, A; G) = \varprojlim H^*(K(\mathcal{U}), K'(\mathcal{V}); G)$.

The **relative Alexander cohomology group** $\bar{H}^*(X, A; G)$ is defined to be the cohomology group of the cochain complex which is the kernel of the cochain mapping $i^\#: \Phi(X; G) \rightarrow \Phi(A; G)$ induced by inclusion. There is a natural isomorphism $\check{H}^*(X, A; G) \cong \bar{H}^*(X, A; G)$.

The relative Čech (co)homology groups satisfy the properties analogous to the relative singular (co)homology groups except the exactness property for homology (\rightarrow Section Q). In certain cases, the excision property is strengthened for Čech (co)homology. For example, we have the following theorem: Assume that X and Y are compact Hausdorff

spaces, A and B are closed subsets of X and Y , respectively, and $f: (X, A) \rightarrow (Y, B)$ is a continuous mapping which maps $X - A$ onto $Y - B$ homeomorphically. Then $f_*: \check{H}_*(X, A; G) \cong \check{H}_*(Y, B; G)$ and $f^*: \check{H}^*(Y, B; G) \cong \check{H}^*(X, A; G)$ hold.

N. Fundamental Classes of Manifolds

For a topological space X and a point x of X , the **local homology groups** $H_*(X, X - x)$ represent a topological property of X around x .

The notion of \dagger orientation for differentiable manifolds and triangulable manifolds generalizes to \dagger topological manifolds by using local homology groups as follows. Let M be an n -dimensional (topological) manifold with \dagger boundary ∂M . If x is a point of the interior $M_0 = M - \partial M$, then $H_q(M, M - x) \cong H_q(\mathbf{R}^n, \mathbf{R}^n - 0)$ is \mathbf{Z} for $q = n$ and is 0 for $q \neq n$. We define a **local orientation** o_x for M at $x \in M_0$ to be a choice of one of the two possible generators for $H_n(M, M - x)$, and we then define an **orientation** for M to be a function which assigns to each $x \in M_0$ a local orientation o_x which varies continuously with x in the following sense: For each x there should exist a compact neighborhood $N \subset M_0$ and an element $o_N \in H_n(M, M - N)$ such that $i_{y*}(o_N) = o_y$ for each $y \in N$, where $i_y: (M, M - N) \subset (M, M - y)$. If there is an orientation for M , then M is said to be **orientable**, and the pair of M and an orientation is called an **oriented manifold**. If M is a nonorientable manifold without boundary, the set of local orientations for M forms an orientable manifold doubly covering M , called the **orientation manifold** of M .

If M is an oriented n -dimensional manifold, then for any compact subset K of M there is a unique element $o_K \in H_n(M, (M - K) \cup \partial M)$ such that $i_{x*}(o_K) = o_x$ for each $x \in K \cap M_0$, where $i_x: (M, (M - K) \cup \partial M) \subset (M, M - x)$. The element o_K is called the **fundamental homology class around K** . In particular, if M is itself compact, $o_M \in H_n(M, \partial M)$ is usually denoted by $[M]$ and is called the **fundamental homology class** of M . A connected compact n -dimensional manifold M is orientable if and only if $H_n(M, \partial M) \neq 0$, and in this case $H_n(M, \partial M)$ is a free cyclic group generated by a fundamental class $[M]$. If M is an orientable compact n -dimensional manifold, then ∂M is an orientable compact $(n - 1)$ -dimensional manifold without boundary, and the boundary homomorphism $\partial_*: H_n(M, \partial M) \rightarrow H_{n-1}(\partial M)$ sends a fundamental class $[M]$ to a fundamental class $[\partial M]$.

An n -dimensional manifold M is orientable if and only if there exists an element $U \in H^n(M \times M, M \times M - dM)$ such that, for each $x \in M_0$,

$j_x^*(U)$ is a generator of $H^n(M, M-x)$, where dM is the diagonal in $M \times M$, and $j_x: (M, M-x) \rightarrow (M \times M, M \times M - dM)$ is given by $j_x(y) = (x, y)$ ($y \in M$). In fact, U corresponds to an orientation which assigns to each $x \in M_0$ a local orientation o_x such that $\langle j_x^*(U), o_x \rangle = 1$. The element U is called the **orientation cohomology class** of M . If M is a compact manifold without boundary, it holds that $\langle d^*(U), [M] \rangle = \chi(M)$, where $d^*: H^n(M \times M, M \times M - dM) \rightarrow H^n(M)$ is induced by the diagonal mapping. The element $d^*(U) \in H^n(M)$ is called the **Euler class** of M .

If we work with the (co)homology groups with coefficients in \mathbb{Z}_2 , the fundamental classes are defined for an arbitrary manifold without making any assumption of orientability. If M is connected and compact, then $H_n(M, \partial M; \mathbb{Z}_2) \cong \mathbb{Z}_2$ is generated by $[M]$.

O. Duality in Manifolds

Let M be a compact n -dimensional manifold, and let M_1, M_2 be compact $(n-1)$ -dimensional manifolds such that $M_1 \cup M_2 = \partial M$ and $M_1 \cap M_2 = \partial M_1 = \partial M_2$. Assume either that M is oriented or that $G = \mathbb{Z}_2$. Then for each q , an isomorphism $D: H^q(M, M_1; G) \cong H_{n-q}(M, M_2; G)$ is defined by $D(\xi) = \xi \frown [M]$. In particular, there are the isomorphisms $D: H^q(M, \partial M; G) \cong H_{n-q}(M; G)$ and $H^q(M; G) \cong H_{n-q}(M, \partial M; G)$, where the cap product is taken with respect to the homomorphism $G \otimes \mathbb{Z} \rightarrow G$ defined by multiplication. This theorem is called the **Poincaré-Lefschetz duality theorem**, and the special case for $\partial M = \emptyset$ is often referred to as **Poincaré duality**.

Poincaré duality implies the following consequences for a compact n -dimensional manifold M without boundary. If M is orientable, then the q th Betti number is equal to the $(n-q)$ th Betti number, and the q th torsion coefficients are equal to the $(n-q-1)$ th torsion coefficients. If n is odd, then $\chi(M) = 0$, and if M is orientable and $n \equiv 2 \pmod{4}$, then $\chi(M)$ is even.

Poincaré duality generalizes to the following duality theorem. Let M be an n -dimensional manifold without boundary, and let K be a compact subset of M . Assume either that M is oriented or that $G = \mathbb{Z}_2$. Then there is an isomorphism $D: \tilde{H}^q(K; G) \cong H_{n-q}(M, M-K; G)$ for any q , which is given as follows: For each open neighborhood W of K , define $D_W: H^q(W; G) \rightarrow H_{n-q}(M, M-K; G)$ by $D_W(\xi) = k_*(\xi \frown k_*^{-1}(o_K))$, where k_* is the excision isomorphism induced by $k: (W, W-K) \hookrightarrow (M, M-K)$. Now D is defined to be the limit of D_W , where W varies over open neighborhoods of K . The inverse of D up to sign is given in terms of the slant

product with the fundamental cohomology class U of M as follows: For each open neighborhood W of K , we define a homomorphism $\gamma_W: H_{n-q}(M, M-W; G) \rightarrow H^q(W; G)$ by $\gamma_W(a) = j^*(U)/a$, where $j^*: H^n(M \times M, M \times M - dM) \rightarrow H^n(W \times (M, M-W))$ is induced by inclusion. Then, passing to the limit, these γ_W define the desired one.

If we take an n -sphere S^n as M in the above duality theorem and use the homology exact sequence of $(S^n, S^n - K)$, then we have the following **Alexander duality theorem** (*Trans. Amer. Math. Soc.*, 23 (1922)): If K is a closed subset of S^n , then the q th reduced Čech cohomology group of K is isomorphic to the $(n-q-1)$ th reduced singular homology group of $S^n - K$ for any coefficient group G and any q . In particular, if K is a neighborhood retract, $\tilde{H}^q(K; G) \cong \tilde{H}_{n-q-1}(S^n - K; G)$ holds. This shows that $H_*(S^n - K)$ depends only on K and not on the way K is embedded in S^n . The Alexander duality theorem for $n=2$ and $K=S^1$ gives the classical \dagger Jordan curve theorem.

In view of the duality theorems, certain classical definitions in the homology of manifolds can be given in terms of cohomology. For example, if $f: M \rightarrow M'$ is a continuous mapping of oriented closed manifolds, then the **Umkehr homomorphism** or **Gysin homomorphism** $f^!: H_q(M'; G) \rightarrow H_{q+d}(M; G)$ ($d = \dim M - \dim M'$) (W. Gysin, *Comment. Math. Helv.*, 14 (1941)) can be defined by $D \circ f^! = f^* \circ D$. In cohomology we have $f!: H^q(M; G) \rightarrow H^{q-d}(M'; G)$. Similarly, if M is an oriented n -dimensional closed manifold and $a \in H_p(M)$, $b \in H_q(M)$, then the **intersection product** $a \cdot b \in H_{p+q-n}(M)$ of Lefschetz can be defined by $a \cdot b = D^{-1}a \frown b = D(D^{-1}a \smile D^{-1}b)$. If $p+q=n$, the number $a \cdot b \in H_0(M) \cong \mathbb{Z}$ is called the **intersection number** of a and b . The classical definitions are still meaningful today, since they are closer to geometric intuition and therefore possess considerable heuristic value. For example, the following fact serves to compute cup products in manifolds. If M is an oriented closed differentiable manifold and $a, b \in H_*(M)$ are represented by closed submanifolds N_1, N_2 which intersect \dagger transversally, then $\pm a \cdot b$ is represented by $N_1 \cap N_2$ [11]. See [12] for a rigorous discussion of classical intersection theory.

P. Cohomology with Compact Supports

Let X be a topological space. A subset V of X is said to be **cobounded** if $\overline{X-V}$ is compact. A singular q -cochain $u \in \text{Hom}(S_q(X), G)$ is said to have **compact support** if there exists a cobounded set V such that $u(\sigma) = 0$ for every singular q -simplex σ in V . The singular cochains with compact support form a subcom-

plex of the cochain complex $\text{Hom}(S(X), G)$. The cohomology group of this subcomplex is denoted by $H_c^*(X; G)$ and is called the **singular cohomology group of X with compact supports**. There is an isomorphism $H_c^*(X; G) \cong \varinjlim H^*(X, V; G)$, where V varies over cobounded subsets of X .

Let K be a simplicial complex. A q -cochain $u \in \text{Hom}(C_q(K), G)$ is called a **finite cochain** of K if $u(\sigma) = 0$ except for a finite number of oriented q -simplexes σ of K . If K is a \dagger locally finite simplicial complex, then finite cochains of K form a subcomplex of the cochain complex $\text{Hom}(C(K), G)$ whose cohomology group is isomorphic to $H_c^*(|K|; G)$.

Let X be a \dagger locally compact Hausdorff space, and let $X \cup \{\infty\}$ denote the \dagger one-point compactification of X . Then the **Čech cohomology group of X with compact supports**, denoted by $\check{H}_c^*(X; G)$ is defined to be the reduced Čech cohomology group of $X \cup \{\infty\}$ with coefficients in G . There is an isomorphism $\check{H}_c^*(X; G) \cong \varinjlim \check{H}^*(X, V; G)$, where V varies over cobounded subsets of X . If X is a manifold or a CW complex, then $H_c^*(X; G) \cong \check{H}_c^*(X; G)$. If X is a compact Hausdorff space and A is closed in X , then $\check{H}_c^*(X - A; G) \cong H^*(X, A; G)$. The Alexander-Kolmogorov construction gives a direct approach to $\check{H}_c^*(X; G)$ [10, 13].

A \dagger proper continuous mapping $f: X \rightarrow Y$ of locally compact Hausdorff spaces induces homomorphisms $f^*: H_c^*(Y; G) \rightarrow H_c^*(X; G)$ and $f^*: \check{H}_c^*(Y; G) \rightarrow \check{H}_c^*(X; G)$, and if $f, f': X \rightarrow Y$ are properly homotopic, then they induce the same homomorphisms.

The cohomology with compact supports is useful in order to extend results in the cohomology of compact spaces to noncompact spaces. For example, the conclusion of the duality theorem on a compact set $K \subset M$ in Section O generalizes to the case of a closed set $K \subset M$ as follows: There is an isomorphism $\check{H}_c^q(K; G) \cong H_{n-q}(M, M - K; G)$ for any q . This implies the following generalization of Poincaré duality: $H_c^q(M; G) \cong H_{n-q}(M; G)$ holds for an orientable n -dimensional manifold M without boundary.

There are homology theories associated with the cohomology theories with compact supports [13].

Q. Eilenberg-Steenrod Axioms

Let H^* be a collection of the following three functions: (1) A function assigning to each topological pair (X, A) and each integer q an Abelian group $H^q(X, A)$. (2) A function assigning to each continuous mapping $f: (X, A) \rightarrow (Y, B)$ and each integer q a homomorphism

$f^*: H^q(Y, B) \rightarrow H^q(X, A)$. (3) A function assigning to each topological pair (X, A) and each integer q a homomorphism $\delta^*: H^q(A) \rightarrow H^{q+1}(X, A)$. Then H^* is called a **cohomology theory on the category of topological pairs** if the following seven axioms are satisfied [7]. (i) $1_* = 1$, where 1 is identity. (ii) $(g \circ f)^* = f^* \circ g^*: H^q(Z, C) \rightarrow H^q(X, A)$ for continuous mappings $f: (X, A) \rightarrow (Y, B)$ and $g: (Y, B) \rightarrow (Z, C)$. (iii) Homotopy axiom: If $f, f': (X, A) \rightarrow (Y, B)$ are homotopic, then $f_* = f'_*: H^q(Y, B) \rightarrow H^q(X, A)$. (iv) Exactness axiom: The sequence $\dots \xrightarrow{\delta^*} H^q(X, A) \xrightarrow{i^*} H^q(X) \xrightarrow{i^*} H^q(A) \xrightarrow{\delta^*} H^{q+1}(X, A) \xrightarrow{j^*} \dots$ is exact, where $i: A \subset X$ and $j: (X, \emptyset) \subset (X, A)$. (v) $f^* \circ \delta^* = \delta^* \circ (f|A)^*: H^q(B) \rightarrow H^{q+1}(X, A)$ for a continuous mapping $f: (X, A) \rightarrow (Y, B)$. (vi) Excision axiom: If U is an open set of X such that $\bar{U} \subset \text{Int } A$, then $i^*: H^q(X, A) \cong H^q(X - U, A - U)$, where i is the inclusion. (vii) Dimension axiom: $H^q(pt) = 0$ if $q \neq 0$. Axioms (i)–(vii) are called the **Eilenberg-Steenrod axioms**, and the group $H^0(pt)$ is called the **coefficient group** of the cohomology theory H^* .

A cohomology theory on the category of pairs of compact Hausdorff spaces is defined similarly. A cohomology theory on the category of CW pairs (or finite CW pairs) is defined similarly except that axiom (vi) is replaced by the following excision axiom: If $\{X_1, X_2\}$ is a couple of subcomplexes of a CW complex, then $i^*: H^q(X_1 \cup X_2, X_2) \cong H^q(X_1, X_1 \cap X_2)$, where i is the inclusion. Two cohomology theories H^* and H'^* on the same category are **isomorphic** if there is an isomorphism $h_q: H^q(X, A) \cong H'^q(X, A)$ for each (X, A) and each q , and they commute with f^* and δ^* . A homology theory on various categories is defined similarly by dualization.

A singular (co)homology theory with coefficients in G is an example of a (co)homology theory on the category of topological pairs. The Čech cohomology groups with coefficients in G can be made into a cohomology theory on the category of topological pairs. However, the Čech homology groups do not constitute a homology theory on the category of topological pairs; the homology sequence of any pair (X, A) is defined, but it can be proved only that the composite of any two successive homomorphisms is zero. The Čech homology groups with coefficients in a field constitute a homology theory on the category of compact Hausdorff pairs. The Alexander cohomology groups constitute a cohomology theory on the same category of topological pairs, and it is isomorphic to the Čech cohomology theory if their coefficient groups are isomorphic [10].

The Čech (co)homology constitutes a (co)homology theory on the category of CW pairs, and it is isomorphic to the singular (co)homology theory on the same category if

the coefficient groups are isomorphic. (Co-)homology theories on the category of finite CW pairs are determined, up to isomorphisms, by their coefficient groups. This fact is called the **uniqueness theorem of homology theory** on the category of finite CW pairs. Cohomology theories on the category of pairs of compact Hausdorff spaces which satisfy the following continuity axiom are determined, up to isomorphisms, by their coefficient groups: If $\{(X_\lambda, A_\lambda)\}$ is an inverse system of pairs of compact Hausdorff spaces, then $H^q(\varprojlim X_\lambda, \varprojlim A_\lambda) \cong \varprojlim H^q(X_\lambda, A_\lambda)$. The Čech cohomology theory satisfies this axiom.

During recent years, many (co)homology theories have been developed which satisfy the first six Eilenberg-Steenrod axioms but fail to satisfy the dimension axiom. These are called **generalized (co)homology theories**, and include various $\dagger K$ -theories, \dagger bordism theories, and \dagger stable homotopy theories (\rightarrow 202 Homotopy Theory).

R. Homology with Coefficients in Local Systems

N. E. Steenrod (*Ann. Math.*, (2) 44 (1943)) introduced the (co)homology group with coefficients in a local system of Abelian groups, which is useful in \dagger obstruction theory and in the homology theory of \dagger fiber spaces.

A **local system** \mathfrak{G} of Abelian groups on a topological space X is a set of Abelian groups G_x , one for each $x \in X$, together with an isomorphism $l^*: G_{l(0)} \rightarrow G_{l(1)}$ for each \dagger path $l: [0, 1] \rightarrow X$ subject to the following conditions: (1) If two paths l and l' are homotopic with endpoints fixed, then $l^* = l'^*$. (2) If l and m are paths such that $l(1) = m(0)$, then $(l \cdot m)^* = m^* \circ l^*$, where $l \cdot m$ denotes the \dagger product of l and m . An example is provided by the \dagger homotopy groups $\pi_n(X, x)$ for $n \geq 2$. Let M be an n -dimensional topological manifold. Then $x \rightarrow H_n(M, M - x)$ is a local system of infinite cyclic groups. It is called the **orientation sheaf** of M . A local system \mathfrak{G} is said to be trivial if $l^* = l'^*$ for any paths l, l' with the same initial and final points.

Given a local system \mathfrak{G} of Abelian groups on a topological space X , a chain complex $S(X; \mathfrak{G}) = \{S_q(X; \mathfrak{G}), \partial_q\}$ is defined as follows: If $q < 0$, then $S_q(X; \mathfrak{G}) = 0$, and if $q \geq 0$, then $S_q(X; \mathfrak{G})$ is the Abelian group of formal finite sums $\sum g_\sigma \sigma$, where $\sigma: \Delta^q \rightarrow X$ are singular q -simplexes in X and $g_\sigma \in G_{\sigma(1,0,\dots,0)}$; the boundary operator $\partial_q: S_q(X; \mathfrak{G}) \rightarrow S_{q-1}(X; \mathfrak{G})$ is given by $\partial_q(g_\sigma \sigma) = l_\sigma^*(g_\sigma) \sigma \circ \varepsilon_0 + \sum_{i=1}^q (-1)^i g_\sigma \sigma \circ \varepsilon_i$, where $\sigma \circ \varepsilon_i$ is the i th face of σ , and $l_\sigma: [0, 1] \rightarrow X$ is given by $l_\sigma(t) = \sigma(1-t, t, 0, \dots, 0)$. The homology group of the chain complex $S(X; \mathfrak{G})$

is denoted by $H_*(X; \mathfrak{G})$ and is called the **singular homology group of X with coefficients in \mathfrak{G}** .

Similarly, a cochain complex $S^*(X; \mathfrak{G}) = \{S^q(X; \mathfrak{G}), \delta^q\}$ is defined as follows: If $q < 0$, then $S^q(X; \mathfrak{G}) = 0$, and if $q \geq 0$, then $S^q(X; \mathfrak{G})$ is the Abelian group of functions u assigning to every singular q -simplex σ in X an element $u(\sigma) \in G_{\sigma(1,0,\dots,0)}$; the coboundary operator $\delta^q: S^q(X; \mathfrak{G}) \rightarrow S^{q+1}(X; \mathfrak{G})$ for $q \geq 0$ is given by $(\delta^q u)(\sigma) = l_\sigma^{*-1} u(\sigma \circ \varepsilon_0) + \sum_{i=1}^{q+1} (-1)^i u(\sigma \circ \varepsilon_i)$, where σ is a singular $(q+1)$ -simplex in X . The cohomology group of the cochain complex $S^*(X; \mathfrak{G})$ is denoted by $H^*(X; \mathfrak{G})$ and is called the **singular cohomology group of X with coefficients in \mathfrak{G}** .

If \mathfrak{G} is trivial, then the (co)homology group with coefficients in \mathfrak{G} coincides with the (co-)homology group with coefficients in $G \cong G_x$. The various notions and theorems on the ordinary (co)homology can be extended to (co)homology with coefficients in \mathfrak{G} . The Čech (co)homology group with coefficients in \mathfrak{G} is also defined [10]. The cohomology groups with coefficients in \mathfrak{G} are generalized to the cohomology groups with coefficients in a sheaf [10, 14] (\rightarrow 383 Sheaves).

202 (IX.9) Homotopy Theory

A. General Remarks

Given a topological space X , we utilize the concept of homotopy to define the †fundamental group, homotopy groups, and cohomotopy groups of X . These groups, together with (co)homology groups, are useful tools in topology.

Since the research of H. Hopf, W. Hurewicz, and H. Freudenthal in the 1930s, homotopy theory has made rapid progress and now plays an important role in topology.

B. Homotopy

If a family $f_t: X \rightarrow Y$ ($t \in I = \{t | 0 \leq t \leq 1\}$) of †continuous mappings from a †topological space X into a topological space Y is also continuous with respect to t , that is, if the mapping F from the product space $X \times I$ into Y defined by $F(x, t) = f_t(x)$ ($x \in X, t \in I$) is continuous, then $\{f_t\}$ or F is called a **homotopy**. In this case, f_0 and f_1 are said to be **homotopic**. This relation between f_0 and f_1 is indicated by $f_0 \simeq f_1: X \rightarrow Y$, or simply $f_0 \simeq f_1$, and is called

the relation of homotopy. Denote by Y^X the set of all continuous mappings from X into Y . The homotopy relation is an †equivalence relation on Y^X , and the equivalence class $[f]$ of a mapping $f: X \rightarrow Y$ is called the **homotopy class** (or **mapping class**) of f . The set of all homotopy classes of mappings of X into Y is called the **homotopy set** and is denoted by $\pi(X; Y)$ or $[X, Y]$. A function γ of continuous mappings $f \in Y^X$ is called a **homotopy invariant** if $f \simeq g$ implies $\gamma(f) = \gamma(g)$. When X consists of a point $*$ we write $\pi(*; Y) = \pi_0(Y)$. If all continuous mappings in Y^X are homotopic to each other, we write $\pi(X; Y) = 0$; $\pi_0(Y) = 0$ means that Y is †arcwise connected. A mapping f from a compact space into an n -dimensional sphere S^n is called essential if any mapping g homotopic to f satisfies $g(X) = S^n$. A mapping is inessential if and only if it is homotopic to the constant mapping.

These concepts are generalized as follows: Let A_i and B_i ($i = 1, 2, \dots$) be subspaces of X and Y , respectively, and denote by $Y^X(A_1, A_2, \dots; B_1, B_2, \dots)$ the set of continuous mappings $f \in Y^X$ satisfying $f(A_i) \subset B_i$. If a homotopy $\{f_t\}$ is such that $f_t \in Y^X(A_i; B_i)$, then $\{f_t\}$ is called a **restricted homotopy** with respect to A_i, B_i or a homotopy from a system of spaces (X, A_1, A_2, \dots) into a system of spaces (Y, B_1, B_2, \dots) . The notation $f_0 \simeq f_1: (X, A_1, A_2, \dots) \rightarrow (Y, B_1, B_2, \dots)$ and the homotopy set $\pi(X, A_1, A_2, \dots; Y, B_1, B_2, \dots)$ are defined accordingly.

For the composite $g \circ f \in Z^X(A_i; C_i)$ of $f \in Y^X(A_i; B_i)$ and $g \in Z^X(B_i; C_i)$, $f \simeq f'$ and $g \simeq g'$ imply $g \circ f \simeq g' \circ f'$. Thus the **composite** $\beta \circ \alpha = [g \circ f] \in \pi(X, A_i; Z, C_i)$ of $[f] = \alpha \in \pi(X, A_i; Y, B_i)$ and $[g] = \beta \in \pi(Y, B_i; Z, C_i)$ is defined. By putting $g_*[f] = [g \circ f] = f^*[g]$ we induce two mappings,

$$g_*: \pi(X, A_i; Y, B_i) \rightarrow \pi(X, A_i; Z, C_i),$$

$$f^*: \pi(Y, B_i; Z, C_i) \rightarrow \pi(X, A_i; Z, C_i).$$

Then $f \simeq f'$ implies $f^* = f'^*$ and $g \simeq g'$ implies $g_* = g'_*$. Also $(g \circ f)_* = g_* \circ f_*$, $(g \circ f)^* = f^* \circ g^*$, and $h^* \circ g_* = g_* \circ h^*$, where $h \in X^W(D_i; A_i)$.

The **category of pointed topological spaces** is defined to be the †category in which each object X , which is a topological space, has a point fixed as a **base point** and each mapping $X \rightarrow Y$ carries the base point of X to the base point of Y . In this category, we define a homotopy set, denoted by $\pi(X; Y)_0$ or $[X; Y]_0$, as follows: Denoting the base points by $*$, we have $\pi(X, A_i, *; Y, B_i, *) = \pi(X, A_i; Y, B_i)_0$. A continuous mapping f homotopic to the constant mapping $X \rightarrow * \in Y$ is said to be **homotopic to zero** (or **null-homotopic**). This is indicated by $f \simeq 0$, and $\pi(X; Y)_0 = 0$ means that all continuous mappings are homotopic to zero. Let S^0 be a set of two points; then

$\pi(X; S^0)_0 = 0$ means that X is \dagger connected. In contrast to these specific homotopies, the usual homotopy is sometimes called a **free homotopy**.

Suppose that a homotopy $\{f_t\}$ ($f_t: X \rightarrow Y$) is such that the restriction of f_t to a subspace A of X is stationary, that is, $f_t(a) = f_0(a)$ ($a \in A$, $t \in I$). Then f_0, f_1 are said to be **homotopic relative to A** , indicated by $f_0 \simeq f_1$ (rel. A). If a homotopy $\{f_t\}$ ($f_t: X \rightarrow Y$) is such that each f_t is a homeomorphism into Y , then $\{f_t\}$ is called an **isotopy** and f_0 is called **isotopic** to f_1 (\rightarrow 235 Knot Theory).

Research done by L. E. Brouwer, H. Hopf, W. Hurewicz, K. Borsuk, L. S. Pontryagin, and S. Eilenberg has contributed to the theory of homotopy, an important field of topology still in the process of development.

C. Mapping Spaces

We endow the set Y^X of all continuous mappings $f: X \rightarrow Y$, with the \dagger compact-open topology. The topological space Y^X is called a **mapping space**. In particular we denote Y^I ($0, 1; *, *$) ($* \in Y$) by $\Omega(Y) = \Omega(Y, *)$ and call it the **space of closed paths** (or **loop space**) of Y . Two points f, g of Y^X are connected by a \dagger path in Y^X if and only if $f \simeq g: X \rightarrow Y$. Thus $\pi_0(Y^X) = \pi(X; Y)$ and $\pi_0(Y^X(A_i; B_i)) = \pi(X, A_i; Y, B_i)$.

D. Retracts

Let A be a subspace of a topological space X . If there exists an $f \in A^X$ such that the restriction $f|_A$ is the identity mapping of A , then A is called a **retract** of X , and f a **retraction**. If A is a retract of X , any continuous mapping of A into any topological space can be extended to a continuous mapping of X . If A is a retract of some neighborhood $U(A)$, A is called a **neighborhood retract** or **NR** of X . If for any \dagger homeomorphism of a metric space A onto a closed subspace A_0 of any metric space X , A_0 is a retract (neighborhood retract) of X , then A is called an **absolute retract** or **AR** (**absolute neighborhood retract** or **ANR**). For example, an n -dimensional simplex or an n -dimensional Euclidean space is an AR. If a retraction f is homotopic to the identity mapping of X (resp. $U(A)$), we call A a **deformation retract** (**neighborhood deformation retract**) of X . Moreover, if $f \simeq 1_X$ (rel. A), then A is called a **strong deformation retract**. In particular, if a point x_0 is a (strong) deformation retract of X , we say that X is **contractible** to the point x_0 . For example, any \dagger polyhedron P and any compact n -dimensional \dagger topological manifold are ANRs; any polyhedron P_0 contained in P in a strong deformation retract of some neighbor-

hood in P . X is called **locally contractible** if each point x of X has a contractible neighborhood U of x .

E. The Extension Property

Let X, Y be topological spaces, $A \subset X$, $f_0, f_1 \in Y^X$, and $\{g_t: A \rightarrow Y\}$ a homotopy such that $g_t = f_t|_A$ ($t = 0, 1$). We can extend $\{g_t\}$ to a homotopy $\{f_t\}$ of X if and only if the mapping $F: (X \times 0) \cup (A \times I) \cup (X \times 1) \rightarrow Y$ defined by $F(x, i) = f_i(x)$, $F(a, t) = g_t(a)$ can be extended to a continuous mapping sending $X \times I$ into Y . Therefore the problem of whether $f_0 \simeq f_1$ can be reduced to the problem of whether a continuous mapping defined on a subspace can be extended to the whole space. If for any homotopy $\{g_t: A \rightarrow Y\}$ and any continuous mapping $f_0: X \rightarrow Y$ into any topological space Y satisfying $f_0|_A = g_0$ there exists a homotopy $\{f_t: X \rightarrow Y\}$ satisfying $f_t|_A = g_t$, then we say that (X, A) has the **homotopy extension property**. This occurs if and only if $(X \times 0) \cup (A \times I)$ is a retract of $X \times I$. A pair (X, A) of ANRs, where A is closed in X , and a pair (P, P_0) with P a \dagger CW complex and P_0 a subcomplex of P have this property. Given a continuous mapping $h: B \rightarrow A$ of a subspace B of a topological space Y into a topological space A , we identify $b \in B$ with $h(b) \in A$ in the \dagger direct sum $A \cup Y$ and obtain the \dagger identification space denoted by $A \cup_h Y$, which is called an **attaching space** under h . If (Y, B) has the homotopy extension property, then $(Y \times X, B \times X)$ and $(A \cup_h Y, A)$ also have the same property. When A consists of a point $*$, we write $* \cup_h Y = Y/B$ and call the space Y/B a **space smashing** (shrinking or pinching) B to a point. If $Y = B \times I$, $B = B \times 0$, then we call $A \cup_h (B \times I)$ a **mapping cylinder** of h , $(A \cup_h (B \times I))/(B \times 1)$ a **mapping cone** of h , and the mapping cylinder and mapping cone of $h: B \rightarrow *$ the **cone over B** and **suspension** of B , respectively.

F. Homotopy Type

For systems $(X, A_i), (Y, B_i)$ of topological spaces, if there exist $f \in Y^X(A_i; B_i)$, $g \in X^Y(B_i; A_i)$ such that $g \circ f$ and $f \circ g$ are homotopic to the identity mappings of (X, A_i) and (Y, B_i) , respectively, then we say that (X, A_i) and (Y, B_i) have the same **homotopy type** or are **homotopy equivalent**. Such mappings f and g are called **homotopy equivalences**. For a homotopy equivalence f , the induced mappings f_* and f^* are bijective. Therefore, in homotopy theory, systems of spaces having the same homotopy type are considered equivalent. If A is a deformation retract of X , then A and X have the same homotopy type, and the

injection of A into X and the retraction of X onto A are homotopy equivalences. A contractible space has the same homotopy type as a point. Spaces having the same homotopy type have isomorphic homotopy groups and \dagger (co)homology groups. Since the mapping cylinder $Z_f = Y \cup_f (X \times I)$ of $f \in Y^X$ contains Y as its deformation retract, it has the same homotopy type as Y . By this homotopy equivalence, f can be replaced by the injection of $X \times 1$ into Z_f . If to each topological space there corresponds a value (which may be some element of \mathbf{R} or some algebraic structure) and the values are the same for homotopy equivalent spaces, then the value is called a **homotopy type invariant**. A homotopy type invariant is a \dagger topological invariant; for example, $\pi(X; Y)$ is a homotopy type invariant of X . If a continuous mapping $f: X \rightarrow Y$ induces isomorphisms of the homotopy groups of each \dagger arcwise connected component, then f is called a **weak homotopy equivalence**. Conversely, if X and Y are CW complexes, then a weak homotopy equivalence is a homotopy equivalence (J. H. C. Whitehead).

Now we consider the category of pointed topological spaces. Let A and B be pointed topological spaces. Then the \dagger direct sum in this category is the **one-point union** (or **bouquet**) $A \vee B$ obtained from the disjoint union $A \cup B$ by identifying two base points $*_A$ and $*_B$. $A \vee B$ is identified with the subspace $(A \times *_B) \cup (*_A \times B)$ in $A \times B$. The **reduced join** (or **smash product**) of A, B is the space obtained from $A \times B$ by smashing its subspace $A \vee B$ to a point and is denoted by $A \wedge B$. We call $A \wedge S^1$ the **(reduced) suspension** of A and denote it by SA . Repeating the suspension n times, we have the **n -fold reduced suspension** of A . We call $CA = A \wedge I$ ($I = [0, 1]$) the **reduced cone** of A (I has the base point 1). For a continuous mapping $f: X \rightarrow Y$, the space obtained by identifying each point $(x, 0)$ of the base of CX with $f(x) \in Y$ is called the **reduced mapping cone** and is denoted by $C_f = Y \cup_f CX$. The **reduced join** (or **smash product**) of mappings $f: Y \rightarrow X$ and $f': Y' \rightarrow X'$ is the mapping $f \wedge f': Y \wedge Y' \rightarrow X \wedge X'$ induced from the product mapping $f \times f': Y \times Y' \rightarrow X \times X'$. The reduced join of $f: Y \rightarrow X$ and $1: S^1 \rightarrow S^1$ (identity mapping) is written as $Sf = f \wedge 1$ and is called the **suspension** of f .

G. Puppe Exact Sequences

For $f: X \rightarrow Y$ and $g: Y \rightarrow Z$, we have $g \circ f \simeq 0$ if and only if g can be extended to a continuous mapping from C_f into Z . In other words, the sequence

$$\pi(C_f; Z)_0 \xrightarrow{i^*} \pi(Y; Z)_0 \xrightarrow{f^*} \pi(X; Z)_0$$

is exact (i.e., $\text{Im } i^* = \text{Ker } f^* = f^{*-1}(0)$, where $i: Y \rightarrow C_f$ is the canonical inclusion and 0 is the class of the constant mapping). The inclusion $i: Y \rightarrow C_f$ gives rise to the reduced mapping cone C_i . We also have the canonical inclusion $i': C_f \rightarrow C_i$. Adding the term $\pi(C_i; Z)_0 \xrightarrow{i'^*}$ to the left-hand side of the sequence above, we have a new exact sequence. Continuing this process, we obtain an exact sequence of infinite length. If X, Y satisfy a suitable condition (e.g., X, Y are CW complexes), then C_i has the same homotopy type as the reduced suspension SX of X ; i'^* is equivalent to $p^*: \pi(SX; Z)_0 \rightarrow \pi(C_f; Z)_0$ induced by a mapping $p: C_f \rightarrow SX$ smashing Y to a point; and furthermore C_p has the same homotopy type as SY , and the inclusion $i_0: SX \rightarrow C_p$ is equivalent to the suspension $Sf: SX \rightarrow SY$ of f . Thus the following **Puppe exact sequence** is obtained:

$$\begin{aligned} \dots \xrightarrow{Sp^*} \pi(SC_f; Z)_0 \xrightarrow{Si^*} \pi(SY; Z)_0 \xrightarrow{Sf^*} \pi(SX; Z)_0 \\ \xrightarrow{p^*} \pi(C_f; Z)_0 \xrightarrow{i'^*} \pi(Y; Z)_0 \xrightarrow{f^*} \pi(X; Z)_0. \end{aligned}$$

In this exact sequence, if Y is a CW complex, X is a subcomplex of Y , and f is the inclusion $i: X \rightarrow Y$, then $C_i = C_f = Y \cup C_X$ is homotopy equivalent to the space $C_i/CX = Y/X$ obtained by smashing CX to a point, and an exact sequence of the following type is obtained:

$$\begin{aligned} \dots \xrightarrow{Si^*} \pi(SX; Z)_0 \xrightarrow{\delta^*} \pi(Y/X; Z)_0 \xrightarrow{p^*} \pi(Y; Z)_0 \\ \xrightarrow{i'^*} \pi(X; Z)_0. \end{aligned}$$

A sequence equivalent to the sequence $X \xrightarrow{f} Y \xrightarrow{i} C_f$ is called a **cofiber**, for which a similar exact sequence is obtained. For a continuous mapping $f: X \rightarrow Y$, consider the subspace $E_f = \{(x, \varphi) \mid f(x) = \varphi(0)\}$ of the product space $X \times Y^I$. By identifying X with $\{(x, \varphi_x) \mid \varphi_x(I) = f(x)\}$, we can regard X as a deformation retract of E_f . By putting $p_1(x, \varphi) = \varphi(1)$, we obtain a \dagger fiber space (E_f, p_1, Y) . The fiber $T_f = p_1^{-1}(*)$ is called a **mapping track** of f . Using the \dagger covering homotopy property, we see that the sequence

$$\pi(W; T_f)_0 \xrightarrow{p_*} \pi(W; X)_0 \xrightarrow{f_*} \pi(W; Y)_0$$

is exact, where $p(x, \varphi) = x$. This sequence is also extended infinitely to the left as

$$\dots \rightarrow \pi(W; \Omega X)_0 \xrightarrow{(\Omega f)_*} \pi(W; \Omega Y)_0 \xrightarrow{i_*} \pi(W; T_f)_0 \xrightarrow{p_*},$$

where i is the inclusion of the loop space ΩY into T_f and $\Omega f: \Omega X \rightarrow \Omega Y$ is the correspondence of the loops induced from f .

H. Homotopy Sets that Form Groups

If $X = SX'$ or $Y = \Omega Y'$ (or, generally, if Y is a \dagger homotopy associative $\dagger H$ -space having a \dagger homotopy inverse), then $\pi(X; Y)_0$ forms a group. In the general case the product of the

loops induces the product of $\pi(X; \Omega Y)_0$. We represent a point of SX by (x, t) ($x \in X, t \in I$) and define the mapping $\Omega_0 g: X \rightarrow \Omega Y$ for each $g: SX \rightarrow Y$ by $\Omega_0 g(x)(t) = g(x, t)$. Hence an isomorphism $\Omega_0: \pi(SX; Y)_0 \cong \pi(X; \Omega Y)_0$ is obtained. Each of the following pairs of homomorphisms is equivalent: $f_*: \pi(SX; Y)_0 \rightarrow \pi(SX; Y')_0$ and $\Omega f_*: \pi(X; \Omega Y)_0 \rightarrow \pi(X; \Omega Y')_0$; and $h^*: \pi(X'; \Omega Y)_0 \rightarrow \pi(X; \Omega Y)_0$ and $Sh^*: \pi(SX'; Y)_0 \rightarrow \pi(SX; Y)_0$.

If S^n is an n -dimensional sphere, then $\pi_n(X) = \pi(S^n; X)_0$ is the n -dimensional homotopy group (\rightarrow Section J). Let $\pi^n(X) = \pi(X; S^n)_0$. If X is a CW complex of dimension less than $2n - 1$, $\pi^n(X)$ is the cohomotopy group isomorphic to $\pi(X; \Omega S^{n+1})_0$ (\rightarrow Section I). Let K_n be an Eilenberg-MacLane space of type (\mathbb{Z}, n) . Then we have $K_n = \Omega K_{n+1}$, and if (X, A) is a pair of CW complexes, then $\pi(X/A; K_n)_0$ coincides with the cohomology group $H^n(X, A; \mathbb{Z})$. For the classifying space $B_O(B_U)$ of the infinite orthogonal group O (infinite unitary group U) (\rightarrow Section V), $\pi(X/A; B_O)$ ($\pi(X/A; B_U)$) may be considered the KO -group $KO(X, A)$ (K -group $K(X, A)$) (\rightarrow 237 K-Theory).

I. Cohomotopy Groups

K. Borsuk defined a sum of mapping classes of X into S^n (1936), which was named Borsuk's **cohomotopy group** by E. Spanier. Spanier also studied the duality of the cohomotopy group with the homotopy group and its relations to the usual cohomology groups. A cohomotopy group of (X, A) is defined to be $\pi^n(X, A) = \pi(X, A; S^n, *)$, which forms a group if $\dim X/A < 2n - 1$. A mapping $F: X/A \rightarrow S^n \times S^n$ given by $F(x) = (f(x), g(x))$ with $f, g: X/A \rightarrow S^n$ is homotopic to a mapping into $S^n \vee S^n$. If we compose F with a folding mapping of $S^n \vee S^n$ onto S^n , we obtain a mapping that represents the sum $[f] + [g]$. With each homotopy class of a continuous mapping f of an n -dimensional polyhedron K^n into an n -dimensional sphere S^n , we associate the image $f^*(u)$ of the fundamental class $u \in H^n(S^n; \mathbb{Z})$ under the induced homomorphism $f^*: H^n(S^n; \mathbb{Z}) \rightarrow H^n(K^n; \mathbb{Z})$. We then obtain a bijective relation $\pi^n(K^n) \rightarrow H^n(K^n; \mathbb{Z})$, called **Hopf's classification theorem**.

J. Homotopy Groups

Let X be a topological space with a base point $*$, $I^n = \{t = (t_1, t_2, \dots, t_n) \mid 0 \leq t_1, t_2, \dots, t_n \leq 1\}$ be the unit n -cube, and I^n its boundary. Write $\Omega^n(X, *) = X^{I^n}(I^n, *)$ (in particular, $\Omega^1(X, *)$ is the loop space), and denote by $\pi_n(X, *)$ or simply $\pi_n(X)$ the set of arcwise connected components of $\Omega^n(X, *)$, i.e., the homotopy

classes $[f]$. Using the notation of homotopy sets, we have $\pi_n(X, *) = \pi(I^n, I^n; X, *)$. If we choose the constant mapping as the base point $*$ of $\Omega^n(X, *)$, then $\Omega^n(\Omega^n(X, *), *) = \Omega^{n+n}(X, *)$. Thus $\pi_m(\Omega^n(X, *), *) = \pi_{m+n}(X, *)$. Since π_1 is the fundamental group, $\pi_n(X, *) = \pi_1(\Omega^{n-1}(X, *))$ is also a group, called the n -dimensional **homotopy group** of X with base point $*$. "Multiplication" in homotopy groups is defined as follows: Given $f_1, f_2 \in \Omega^n(X, *)$ we define $f_1 + f_2 \in \Omega^n(X, *)$ by

$$(f_1 + f_2)(t) = \begin{cases} f_1(2t_1, t_2, \dots, t_n), & 0 \leq t_1 \leq \frac{1}{2}, \\ f_2(2t_1 - 1, t_2, \dots, t_n), & \frac{1}{2} \leq t_1 \leq 1 \end{cases}$$

(Fig. 1). Then the product or sum of $[f_1]$ and $[f_2]$ is given by $[f_1 + f_2]$. The identity is the class of the constant mapping (denoted by 0), and the inverse of $[f]$ is $[\bar{f}]$, represented by $\bar{f}(t) = f(1 - t_1, t_2, \dots, t_n)$. The space $\Omega^n(X, *)$ is an H -space, where multiplication is given by the correspondence $(f_1, f_2) \rightarrow f_1 + f_2$. Since the fundamental group of an H -space is commutative, $\pi_n(X, *)$ is an Abelian group for $n \geq 2$.

Fig. 1

Fig. 2

Let $S^n = \{t = (t_1, \dots, t_{n+1}) \mid \sum t_i^2 = 1\}$ be the n -sphere, and take $*$ = $(1, 0, \dots, 0)$ as its base point. Suppose that we are given a continuous mapping $\psi_n: (I^n, I^n) \rightarrow (S^n, *)$ such that $\psi_n: I^n - I^n \rightarrow S^n - *$ is homeomorphic. Then the correspondence $\psi_n^*: \pi(S^n; X)_0 \rightarrow \pi_n(X, *)$ determined by $\psi_n^*[g] = [g \circ \psi_n]$ is bijective. Thus we can identify the homotopy group $\pi_n(X, *)$ with $\pi(S^n; X)_0$.

K. Relative Homotopy Groups

Suppose that we are given a topological space X and a subspace A of X sharing the same base point $*$. Identify I^{n-1} with the face $t_n = 0$ of I^n , and let J^{n-1} be the closure of $I^n - I^{n-1}$ (Fig. 2). Denote by $\pi_n(X, A, *)$ the set of homotopy classes of continuous mappings $f: (I^n, I^n, J^{n-1}) \rightarrow (X, A, *)$. Let $\Omega^n(X, A, *)$ be the mapping space consisting of such mappings f , and let $\pi_n(X, A, *) = \pi_0(\Omega^n(X, A, *))$. Since $\Omega^n(\Omega^n(X, A, *), *)$ is homeomorphic to $\Omega^{n+n}(X, A, *)$, we have $\pi_m(\Omega^n(X, A, *), *) \cong \pi_{m+n}(X, A, *)$. Thus $\pi_n(X, A, *)$ is a group for $n \geq 2$ and an Abelian group for $n \geq 3$. This group is called the n -dimensional **relative**

homotopy group of (X, A) with respect to the base point $*$, or simply the n -dimensional homotopy group of (X, A) . In the same manner as in Section J multiplication in this group can be defined using $f_1 + f_2$. Since $\Omega^n(X, *, *)$ and $\Omega^n(X, *)$ are identical, we have $\pi_n(X, *, *) = \pi_n(X, *)$. Hence homotopy groups are special cases of relative homotopy groups.

Let $g: (X, A, *) \rightarrow (Y, B, *)$ be a continuous mapping. Then a correspondence $g_*: \pi_n(X, A, *) \rightarrow \pi_n(Y, B, *)$ is obtained by $g_*[f] = [g \circ f]$, with g_* a homomorphism of homotopy groups for $n \geq 2$ and for $n = 1, A = *$. We call g_* the **homomorphism induced by g** . Let $E^n = \{t = (t_1, \dots, t_n) \mid \sum t_i^2 = 1\}$ be the unit n -cell with boundary S^{n-1} . Utilizing a suitable relative homeomorphism $\psi'_n: (I^n, J^{n-1}) \rightarrow (E^n, *)$, $\psi'_n(I^n) = S^{n-1}$, we obtain a one-to-one correspondence $\psi'^*_n: \pi(E^n, S^{n-1}; X, A)_0 \rightarrow \pi_n(X, A, *)$, and $\Omega^n(X, A, *)$ is homeomorphic (via ψ'_n) to the mapping space $X^{E^n}(S^{n-1}, *, A, *)$.

L. Homotopy Exact Sequences

Given an element $\alpha = [f] \in \pi_n(X, A, *)$, and letting $\partial\alpha = [f|I^{n-1}] \in \pi_{n-1}(A, *)$, we obtain a homomorphism ($n \geq 2$) $\partial: \pi_n(X, A, *) \rightarrow \pi_{n-1}(A, *)$, which is called the **boundary homomorphism**. Furthermore, we have the following exact sequence involving homomorphisms $i_* \cdot j_*$ induced by two inclusions $i: (A, *) \rightarrow (X, *)$, $j: (X, *, *) \rightarrow (X, A, *)$:

$$\begin{aligned} \dots \xrightarrow{\partial} \pi_n(A, *) \xrightarrow{i_*} \pi_n(X, *) \xrightarrow{j_*} \pi_n(X, A, *) \\ \xrightarrow{\partial} \dots \rightarrow \pi_1(X, *) \xrightarrow{j_*} \pi_1(X, A, *) \xrightarrow{\partial} \pi_0(A) \xrightarrow{i_*} \pi_0(X). \end{aligned}$$

This sequence is called the **homotopy exact sequence** of the pair (X, A) . A system of topological spaces $X \supset A \supset B \ni *$ is called a **triple**. In this homotopy exact sequence, if we replace $(A, *)$, $(X, *)$ by $(A, B, *)$, $(X, B, *)$, respectively, we obtain an exact sequence, called the **homotopy exact sequence of the triple** (X, A, B) .

The homotopy group $\pi_n(A \times B)$ of the product space is isomorphic to the direct sum $\pi_n(A) + \pi_n(B)$, and the projections $p(p'): A \times B \rightarrow A(B)$ of the product space induce the projections from $\pi_n(A \times B)$ onto the direct summands $\pi_n(A)$, $\pi_n(B)$. This is a special case of the Hurewicz-Steenrod isomorphism theorem in fiber spaces (\rightarrow 148 Fiber Spaces). Setting $A \vee B = (A \times *) \cup (* \times B)$, we obtain a direct sum decomposition $\pi_n(A \vee B) \cong \pi_n(A) + \pi_n(B) + \pi_{n+1}(A \times B, A \vee B)$. Next we consider a fixed pair (X, A) and move the base point $*$ to investigate its effect on the elements of the homotopy group. Suppose that we are given a path $h: I \rightarrow A$ with terminal point $* = h(1)$ and an element $\alpha \in \pi_n(X, A, *)$ ($\alpha = [f], f: (I^n, I^n, J^{n-1}) \rightarrow (X, A, *)$). By the homotopy extension property, we can construct a homotopy $f_\theta: (I^n, I^n)$

$\rightarrow (X, A)$ satisfying $f_\theta(J^{n-1}) = h(\theta)$ and $f_1 = f$. Then the homotopy class $[f_\theta]$ of f_θ with respect to the base point $*' = h(0)$ is determined only by α and the homotopy class ω of the path h . We denote the homotopy class $[f_\theta]$ by $\alpha^\omega \in \pi_n(X, A, *')$. The correspondence $\alpha \rightarrow \alpha^\omega$ is a group isomorphism, and $(\alpha^\omega)^{\omega'} = \alpha^{\omega\omega'}$. Thus if A is arcwise connected, $\pi_n(X, A, *)$ is isomorphic to $\pi_n(X, A, *')$. Hence, in this case, we may simply write $\pi_n(X, A)$ instead of $\pi_n(X, A, *)$. When $* = *'$, the correspondence $\alpha \rightarrow \alpha^\omega$ determines the action of the group $\pi_1(A, *)$ on $\pi_n(X, A, *)$. Given an element $\alpha \in \pi_n(X, *)$ and a class ω of paths in X , we define $\alpha^\omega \in \pi_n(X, *')$ as for relative homotopy. Specifically, if $\omega \in \pi_1(X, *)$, then $\alpha^\omega - \alpha$ coincides with the Whitehead product $[\omega, \alpha]$ (when $n = 1$, we have $\alpha^\omega \cdot \alpha^{-1} = [\omega, \alpha] = \omega\alpha\omega^{-1}\alpha^{-1}$) (\rightarrow Section P).

A pair (X, A) consisting of a topological space X and an arcwise connected subspace A of X is said to be **n -simple** if the operation of $\pi_1(A)$ on $\pi_n(X, A)$ is trivial. Similarly, an arcwise connected space X is called **n -simple** if the operation of $\pi_1(X)$ on $\pi_n(X)$ is trivial. For example, a pair (X, A) consisting of an H -space X and an H -subspace A is **simple**, i.e., n -simple for each n . If a topological space X satisfies $\pi_i(X) = 0$ ($0 \leq i \leq n$), then X is said to be **n -connected**. 0-connectedness coincides with arcwise connectedness and 1-connectedness means \dagger simple connectedness. S^n is $(n-1)$ -connected. A pair (X, A) is said to be **n -connected** if $\pi_0(A) = \pi_0(X) = \pi_i(X, A) = 0$ ($1 \leq i \leq n$), and (E^n, S^{n-1}) is $(n-1)$ -connected.

M. Homotopy Groups of Triads

Let $(X; A, B, *)$ be a system, called a **triad**, of a topological space X and its subspaces A, B satisfying $A \cap B \ni *$ (base point). Let $\pi_n(X; A, B, *) = \pi_{n-1}(\Omega^1(X, B), \Omega^1(A, A \cap B), *)$ ($n \geq 2$); $\pi_n(X; A, B, *)$ is a group for $n \geq 3$ and an Abelian group for $n \geq 4$. We call $\pi_n(X; A, B, *)$ the **homotopy group of the triad**. From the homotopy exact sequence of the pair, we obtain the following **homotopy exact sequence of the triad**:

$$\begin{aligned} \dots \xrightarrow{\partial} \pi_j(A, A \cap B, *) \xrightarrow{i_*} \pi_j(X, B, *) \\ \xrightarrow{j_*} \pi_j(X; A, B, *) \xrightarrow{\partial} \pi_{j-1}(A, A \cap B, *) \xrightarrow{i_*} \dots \end{aligned}$$

Assume for simplicity that $A \cap B$ is simply connected, $X = \text{Int } A \cup \text{Int } B$ ($\text{Int } A$ is the \dagger interior of A), $(A, A \cap B)$ is m -connected, and $(B, A \cap B)$ is n -connected. Then $(X; A, B)$ is $(m+n)$ -connected, i.e., $\pi_j(X; A, B, *) = 0$ ($2 \leq j \leq m+n$) (**Blakers-Massey theorem**).

Furthermore, in this case we have a replica of the \dagger excision isomorphism in homology theory for $j < m+n$; that is, we have the isomorphism $i_* \cdot \pi_j(A, A \cap B, *) \cong \pi_j(X, B, *)$ in-

duced by the inclusion $i: (A, A \cap B) \rightarrow (X, B)$. On the other hand, $\pi_{m+n+1}(X; A, B, *)$ is isomorphic to $\pi_{m+1}(A, A \cap B, *) \otimes \pi_{n+1}(B, A \cap B, *)$. This shows that the excision isomorphism does not always hold for homotopy groups, an important difference from homology theory. However, if we replace the excision axiom by the Hurewicz-Steinrod isomorphism theorem, which is valid for fiber spaces (\rightarrow 148 Fiber Spaces), then we can construct homotopy theory axiomatically in the same manner as homology theory (\rightarrow 201 Homology Theory).

N. The Hurewicz Isomorphism Theorem

The **Hurewicz homomorphism** τ of $\pi_n(X, A)$ into the n -dimensional integral homology group $H_n(X, A)$ is defined by $\tau([f]) = f_*(\varepsilon_n)$ (where ε_n is a generator of $H_n(I^n, \dot{I}^n)$). Then we have the **Hurewicz isomorphism theorem**: Suppose that the pair (X, A) is n -simple (e.g., $A = *$) and $(n-1)$ -connected. Then we have $H_i(X, A) = 0$ ($i < n$) and the isomorphism $\tau: \pi_n(X, A) \cong H_n(X, A)$ (for $n = 1 \rightarrow 170$ Fundamental Groups). Let X, Y be simply connected topological spaces, and let $f: X \rightarrow Y$ be a continuous mapping. Then the following two conditions are equivalent: (1) $f_*: \pi_i(X) \rightarrow \pi_i(Y)$ is injective for $i < n$ and surjective for $i \leq n$. (2) $f_*: H_i(X) \rightarrow H_i(Y)$ is injective for $i < n$ and surjective for $i \leq n$ (**J. H. C. Whitehead's theorem**).

J.-P. Serre generalized these theorems as follows: A family \mathcal{C} of Abelian groups satisfying condition (i) is called a **class of Abelian groups**: (i) If a sequence $F \rightarrow G \rightarrow H$ of Abelian groups is exact and $F, H \in \mathcal{C}$, then $G \in \mathcal{C}$. Furthermore, we consider the following conditions: (ii) The tensor product $G \otimes F$ of an arbitrary Abelian group F with an element $G \in \mathcal{C}$ also belongs to \mathcal{C} . (ii') If both $F, G \in \mathcal{C}$, then $F \otimes G, \text{Tor}(F, G) \in \mathcal{C}$. (iii) If $G \in \mathcal{C}$, then its i th homology group $H_i(G) \in \mathcal{C}$ ($i > 0$). Condition (ii') is implied by (ii). A homomorphism $f: F \rightarrow G$ is called \mathcal{C} -injective if $\text{Ker } f \in \mathcal{C}$, \mathcal{C} -surjective if $\text{Coker } f = G/\text{Im } f \in \mathcal{C}$, and a \mathcal{C} -isomorphism if f is \mathcal{C} -injective and \mathcal{C} -surjective. Two Abelian groups G and G' are called \mathcal{C} -isomorphic if there exist \mathcal{C} -isomorphisms $f: F \rightarrow G$ and $f': F \rightarrow G'$. In particular, if the class \mathcal{C}_0 consists of only the trivial group 0, then concepts such as \mathcal{C}_0 -isomorphism coincide with the usual concepts of isomorphism, and so on. Let \mathcal{C}_p be the class of finite Abelian groups whose orders are relatively prime to a fixed prime number p . Here, instead of the terms \mathcal{C}_p -isomorphism and so on, we use the terms **mod p isomorphism** and so on. Let \mathcal{D} be a class of finitely generated Abelian groups. Then \mathcal{C}_p satisfies conditions (ii) and (iii), and \mathcal{D} satisfies (ii') and (iii).

We have the following **generalized Hurewicz theorem**: (A) Suppose that a class \mathcal{C} satisfies (ii) and (iii) and we are given a 2-connected pair (X, A) of simply connected spaces X, A . If $\pi_i(X, A) \in \mathcal{C}$ ($i < n$), then $H_i(X, A) \in \mathcal{C}$, and $\tau: \pi_n(X, A) \rightarrow H_n(X, A)$ is a \mathcal{C} -isomorphism. (B) Suppose that $A = *$, \mathcal{C} satisfies conditions (ii') and (iii), and X is simply connected. Then an assertion similar to (A) holds. In particular, a simply connected space X having finitely generated homology groups (e.g., a simply connected finite polyhedron) has finitely generated homotopy groups. As a corollary to theorem (A), we obtain a **generalized Whitehead theorem**. In particular, applying the theorem to the class $\mathcal{D} \cap \mathcal{C}_p$, we obtain the following frequently used theorem: Suppose that we are given simply connected spaces X, Y whose homology groups are finitely generated and $f: X \rightarrow Y$ satisfies $f_*\pi_2(X) = \pi_2(Y)$. Then the following two conditions are equivalent: (1) $f_*: \pi_i(X) \rightarrow \pi_i(Y)$ is a mod p isomorphism for $i < n$ and a mod p surjection for $i = n$. (2) $f_*: H_i(X, \mathbb{Z}_p) \rightarrow H_i(Y, \mathbb{Z}_p)$ is an isomorphism for $i < n$ and a surjection for $i = n$ (where $\mathbb{Z}_p = \mathbb{Z}/p\mathbb{Z}$). The theory above, which makes use of the notion of class \mathcal{C} , is an example of **Serre's \mathcal{C} -theory**. Concepts such as i spectral sequences for fiber spaces and i n-connective fiber spaces are important tools in Serre's \mathcal{C} -theory (\rightarrow 148 Fiber Spaces).

To calculate homotopy groups, we use notions such as exact sequences, fiber spaces, (co)homology groups of n -connective fiber spaces, and i Postnikov systems. Given an arbitrary group (more generally, a Postnikov system), there exists a CW complex having the given group (system) as its homotopy group (Postnikov system) (**realization theorem of homotopy groups**). For an arbitrary arcwise connected topological space X there exist topological spaces (X, n) and continuous mappings $p_n: (X, n+1) \rightarrow (X, n)$ ($n = 1, 2, \dots$) satisfying the following two conditions: (i) $((X, n+1), p_n, (X, n))$ is a fiber space whose fiber is an i Eilenberg-MacLane space. (ii) $(X, 1) = X$, and $((X, n+1), p_1 \circ \dots \circ p_n, X)$ is an n -connective fiber space. The method of obtaining the homotopy group $\pi_n(X) \cong H_n((X, n))$ by computing (co)homology groups of (X, n) is called a **killing method**.

O. Homotopy Operations

Let X, Y, X', Y' be topological spaces. If to each continuous mapping $f \in Y^X$ there corresponds a homotopy class $\Phi(f) \in \pi(X'; Y')$ that is a homotopy invariant of f (satisfying a certain naturality condition), then Φ is called a **homotopy operation**. More generally, we

may consider the case where Φ is a mapping from $\pi(X_1; Y_1) \times \dots \times \pi(X_r; Y_r)$ into $\pi(X'; Y')$. The **naturality** of Φ is defined as follows: Consider the †category \mathcal{C} of topological spaces (or its subcategory). Let $Y = Y'$ be an arbitrary †object of \mathcal{C} , and fix X and X' . In this case, the naturality of $\Phi_Y: \pi(X; Y) \rightarrow \pi(X'; Y)$ is defined to be the commutativity of the diagram:

$$\begin{array}{ccc} \pi(X; Y) & \xrightarrow{\Phi_Y} & \pi(X'; Y) \\ \downarrow g_* & & \downarrow g_* \\ \pi(X; Z) & \xrightarrow{\Phi_Z} & \pi(X'; Z) \end{array}$$

i.e., $g_* \circ \Phi_Y = \Phi_Z \circ g_*$ for an arbitrary †morphism (i.e., continuous mapping) $g: Y \rightarrow Z$ of the category \mathcal{C} . Similarly, when objects Y, Y' of the category \mathcal{C} are fixed and $X = X'$ is an arbitrary object of \mathcal{C} , to say that a homotopy operation $\Phi_X: \pi(X; Y) \rightarrow \pi(X; Y')$ is **natural** means that $h^* \circ \Phi_X = \Phi_{X'} \circ h^*$ for an arbitrary morphism $h: W \rightarrow X$.

We have the following theorem: In the category of topological spaces and continuous mappings, the homotopy operations $\Phi_Y: \pi(X; Y) \rightarrow \pi(X'; Y)$ and the elements of $\pi(X'; X)$ are in one-to-one correspondence. The correspondence is obtained by associating a homotopy operation $\Phi(\beta) = \beta \circ \alpha$ ($\beta \in \pi(X; Y)$) with each $\alpha \in \pi(X'; X)$. Similarly, the homotopy operations $\Phi_X: \pi(X; Y) \rightarrow \pi(X; Y')$ and the elements of $\pi(Y; Y')$ are in one-to-one correspondence. This theorem holds also for the case involving several variables if we consider $\pi(X'; X_1 \vee X_2 \vee \dots)$ or $\pi(Y_1 \times Y_2 \times \dots; Y')$ instead of $\pi(X'; Y)$ or $\pi(X; Y')$. The theorem remains valid if we replace the spaces X, Y by systems of spaces.

P. Homotopy Operations in Homotopy Groups

(1) If X, X' are spheres S^n, S^p with base points and Y, Y' are topological spaces with base points, a homotopy operation $\Phi_Y: \pi_n(Y) \rightarrow \pi_p(Y)$ is said to be of type (n, p) . By the theorem in Section O, the homotopy operations of type (n, p) are in one-to-one correspondence with the elements of the homotopy group of the sphere $\pi_p(S^n)$.

(2) As an example of the 2-variable homotopy operations $\Phi_Y: \pi_m(Y) \times \pi_n(Y) \rightarrow \pi_p(Y)$ of type $(m, n; p)$ we have the Whitehead product defined as follows: Suppose that $\alpha \in \pi_m(Y)$, $\beta \in \pi_n(Y)$ are elements represented by $f: (I^m, i^m) \rightarrow (Y, *)$ and $g: (I^n, i^n) \rightarrow (Y, *)$, respectively. Define a continuous mapping F from the boundary $I^{m+n} = (I^m \times I^n) \cup (i^m \times I^n) \cup (I^m \times i^n)$ into Y by $F(x, y) = f(x)$ for $(x, y) \in I^m \times I^n$ and $F(x, y) = g(y)$ for $(x, y) \in i^m \times I^n$. Since I^{m+n} is homeomorphic to S^{m+n-1} , we can identify them. The homotopy class represented by F is an element of $\pi_{m+n-1}(Y)$ determined by α

and β , denoted by $[\alpha, \beta]$ and called the **Whitehead product** of α and β (J. H. C. Whitehead, *Ann. Math.*, (2) 42 (1941)). The Whitehead product is a homotopy operation of type $(m, n; m+n-1)$. Let $\psi_m: (I^m, i^m) \rightarrow (S^m, *)$ be a mapping that smashes i^m to a point. The product of ψ_m and ψ_n defines a mapping $\psi_{m,n}: S^{m+n-1} \rightarrow S^m \vee S^n = (S^m \times *) \cup (* \times S^n)$. Let $i \in \pi_m(S^m \vee S^n)$, $i' \in \pi_n(S^m \vee S^n)$ be the homotopy classes of the natural inclusions of S^m, S^n into $S^m \vee S^n$; then the homotopy class of $\psi_{m,n}$ is $[i, i']$. G. W. Whitehead showed that a direct sum decomposition $\pi_p(S^m \vee S^n) = i_* \pi_p(S^m) + i'_* \pi_p(S^n) + [i, i']_* \pi_p(S^{m+n-1})$ ($i_*, i'_*, [i, i']_*$ are injective) holds for $1 < p < m+n+\min(m, n)-3$. Furthermore, P. J. Hilton showed that for general $p > 1$, $\pi_p(S^m \vee S^n)$ is the direct sum of the images of injections $i_*, i'_*, [i, i']_*, [[i, i'], i]_*, [[i, i'], i']_*,$ etc. The homotopy operations of type $(m, n; p)$ are in one-to-one correspondence with the elements of $\pi_p(S^m \vee S^n)$; hence such operations can be constructed by means of composition and the Whitehead product. The last proposition is also valid for homotopy operations of type $(m_1, \dots, m_r; p)$. The Whitehead product $[\alpha, \beta]$ ($\alpha \in \pi_m(X)$, $\beta \in \pi_n(X)$) is distributive with respect to α (resp. β) for $m > 1$ ($n > 1$), and we have $[\beta, \alpha] = (-1)^{mn} [\alpha, \beta]$ and $f_* [\alpha, \beta] = [f_* \alpha, f_* \beta]$ for $f: X \rightarrow Y$. Moreover, for $\gamma \in \pi_r(X)$ the **Jacobi identity** holds: $(-1)^{mr} [[\alpha, \beta], \gamma] + (-1)^{mn} [[\beta, \gamma], \alpha] + (-1)^{rn} [[\gamma, \alpha], \beta] = 0$ (M. Nakaoka and H. Toda; H. Uehara and W. S. Massey; Hilton).

Q. Suspensions and Generalized Hopf Invariants

We denote by $\alpha \wedge \beta \in \pi(X \wedge X'; Y \wedge Y')_0$ the class of the reduced join of f, g , where f represents $\alpha \in \pi(X; Y)_0$ and g represents $\beta \in \pi(X'; Y')_0$. We call $\alpha \wedge \beta$ the **reduced join** of α and β . In particular, if $Y = Y' = S^1$, β is the identity mapping of S^1 , and α is represented by f , then $\alpha \wedge \beta$ is called the **suspension** of α and is denoted by $S\alpha$. $S\alpha$ is the class of the suspension Sf of f and belongs to $\pi(SX; SY)_0$, where SX indicates the reduced suspension of X . The suspension $S\alpha$ is often denoted by $E\alpha$ in reference to the German term *Einhängung*. The identity mapping 1 of SY gives rise to an injection $i = \Omega_0 1$ sending Y into the loop space $\Omega(SY)$ determined by the formula $i(y)(t) = (y, t)$. Then we have

$$i_* = \Omega_0 \circ S: \pi(X; Y)_0 \rightarrow \pi(SX; SY)_0 \cong \pi(X; \Omega SY)_0,$$

and S and i_* are equivalent. Let Y^k be the identifying space Y^k / \sim , where Y^k is the product space $Y \times \dots \times Y$ of k copies of Y and \sim

is the equivalence relation determined by

$$(*, y_1, y_2, \dots, y_{k-1}) \sim (y_1, *, y_2, \dots, y_{k-1}) \sim \dots \sim (y_1, \dots, y_{k-1}, *).$$

Denote by $Y_\infty = \bigcup_k Y_k$ the limit space with respect to the injection $Y_{k-1} \rightarrow Y_k$ given by $(y_1, \dots, y_{k-1}) \rightarrow (y_1, \dots, y_{k-1}, *)$ and call it the **reduced product space** of Y . Let Y be a CW complex of 0-section $*$. The mapping $i: Y = Y_1 \rightarrow \Omega SY$ can then be extended to $\bar{i}: Y_\infty \rightarrow \Omega SY$, where \bar{i} is a weak homotopy equivalence. If X is also a CW complex, then $\Omega_0^{-1} \circ i_*: \pi(X; Y_\infty)_0 \rightarrow \pi(SX; SY)_0$ is bijective. By smashing the subset Y of Y_2 , we have $Y \wedge Y = Y_2/Y$. This smashing mapping can be extended to $h: Y_\infty \rightarrow (Y \wedge Y)_\infty$ (I. M. James). Utilizing $h_*: \pi(X; Y_\infty)_0 \rightarrow \pi(X; (Y \wedge Y)_\infty)_0$ and the bijection $\Omega_0^{-1} \circ \bar{i}_*$, we obtain a correspondence $H: \pi(SX; SY)_0 \rightarrow \pi(SX; S(Y \wedge Y)_0)$. We call $H(\alpha)$ the **generalized Hopf invariant** of α . When $X = S^{2n-2}$, $Y = S^{n-1}$, H is equivalent to the Hopf invariant $\gamma: \pi_{2n-1}(S^n) \rightarrow \mathbb{Z}$ (\rightarrow Section U). In general, we have $H \circ S = 0$, and the exactness of $\xrightarrow{S} \xrightarrow{H}$ holds under various conditions.

Denote also by \circ the composition of homotopy classes; then we have $S(\alpha \circ \beta) = S\alpha \circ S\beta$ and $H(\alpha \circ S\beta) = H\alpha \circ S\beta$. Also, $H(S\alpha \circ \beta) = S(\alpha \wedge \alpha) \circ H\beta$. Under the condition $i < 3n - 3$, we have $(\alpha_1 + \alpha_2) \circ \beta = \alpha_1 \circ \beta + \alpha_2 \circ \beta + [\alpha_1, \alpha_2] \circ H(\beta)$ for $\alpha_1, \alpha_2 \in \pi_n(X)$ and $\beta \in \pi_i(S^n)$ (G. W. Whitehead). Thus the composition $\alpha \circ \beta$ is not always left distributive but is always right distributive, and $\alpha \circ \beta$ is left distributive if $\beta = S\beta'$. The composition is defined over the stable homotopy groups G_r of spheres (\rightarrow Section U): $\alpha \circ \beta \in G_{p+q}$ ($\alpha \in G_p, \beta \in G_q$). It is distributive and satisfies $\beta \circ \alpha = (-1)^{pq} \alpha \circ \beta$.

When Y and Y' are Eilenberg-MacLane spaces, B_O , and B_U , we have t cohomology operations on cohomology groups $H^n(-; \mathbb{I})$, KO groups, and K groups, respectively. As typical examples there are t Steenrod square operations $Sq^i: H^n(X; \mathbb{Z}_2) \rightarrow H^{n+i}(X; \mathbb{Z}_2)$, t Steenrod p th power operations $\mathcal{P}^i: H^n(X; \mathbb{Z}_p) \rightarrow H^{n+2i(p-1)}(X; \mathbb{Z}_p)$, t Chern characters $ch^n: K(X) \rightarrow H^{2n}(X; \mathbb{Q})$ (\mathbb{Q} : rational field), t Adams operations $\Phi_i: KO(X) \rightarrow KO(X)$ ($K(X) \rightarrow K(X)$). They are all homomorphisms (\rightarrow 64 Cohomology Operations; 237 K-Theory).

R. Secondary Compositions

Suppose that $\alpha \circ \beta = 0$, $\beta \circ \gamma = 0$ for $\gamma \in \pi(W; X)_0$, $\beta \in \pi(X; Y)_0$, $\alpha \in \pi(Y; Z)_0$. In the commutative diagram of Puppe exact sequences

$$\begin{array}{ccccccc} S\gamma^* & & & & & & \\ \downarrow \downarrow_* & \xrightarrow{p^*} & \downarrow \downarrow_* & \xrightarrow{i^*} & \downarrow \downarrow_* & \xrightarrow{\gamma^*} & \\ \pi(SW; Y)_0 & \rightarrow & \pi(C_\gamma; Y)_0 & \rightarrow & \pi(X; Y)_0 & \rightarrow & \\ S\gamma^* & & & & & & \\ \downarrow \downarrow_* & \xrightarrow{p^*} & \downarrow \downarrow_* & \xrightarrow{i^*} & \downarrow \downarrow_* & \xrightarrow{\gamma^*} & \\ \pi(SW; Z)_0 & \rightarrow & \pi(C_\gamma; Z)_0 & \rightarrow & \pi(X; Z)_0 & \rightarrow & \end{array}$$

the set of elements $\bar{\beta}$ in $\pi(SW; Z)$ such that $p^*(\bar{\beta}) \in \alpha_* i^{*-1}(\beta)$ is denoted by $\{\alpha, \beta, \gamma\}$ and is called a **secondary composition** or **Toda bracket**. If θ, η are elements of $\pi(SW; Y)_0$, $\pi(SX; Z)_0$, respectively, then we have $\{\alpha, \beta, \gamma\} + \alpha_* \theta = \{\alpha, \beta, \gamma\}$, $\{\alpha, \beta, \gamma\} + S\gamma^* \eta = \{\alpha, \beta, \gamma\}$. Hence we may consider the set $\{\alpha, \beta, \gamma\}$ to be a residue class modulo a submodule generated by $\alpha_* \pi(SW; Y)_0$ and $S\gamma^* \pi(SX; Z)_0$.

The secondary composition $\{\alpha, \beta, \gamma\}$ has the following properties: (i) $\{\alpha, \beta, \gamma\}$ is linear with respect to α, β, γ (if the sum is defined); (ii) $\alpha \circ \{\beta, \gamma, \delta\} = \{\alpha, \beta, \gamma\} \circ (-S\delta)$; (iii) $S\{\alpha, \beta, \gamma\} \equiv -\{S\alpha, S\beta, S\gamma\}$; (iv) $\alpha \circ \{\beta, \gamma, \delta\} \equiv \{\alpha \circ \beta, \gamma, \delta\}$, $\{\alpha \circ \beta, \gamma, \delta\} \equiv \{\alpha, \beta \circ \gamma, \delta\}, \dots$; (v) $\{\{\alpha, \beta, \gamma\}, S\delta, S\epsilon\} + \{\alpha, \{\beta, \gamma, \delta\}, S\epsilon\} + \{\alpha, \beta, \{\gamma, \delta, \epsilon\}\} \equiv 0$. Suppose that the spaces X, Y, Z, W are spheres. Then by (iii) the secondary composition $\{\alpha, \beta, \gamma\} \in G_{p+q+r+1}/(\alpha \circ G_{q+r+1} + \gamma \circ G_{p+q+1})$ is defined in the stable homotopy groups $G_r = \lim_{n \rightarrow \infty} \pi_{n+r}(S^n)$ of spheres. From this we obtain (vi) $\{\gamma, \beta, \alpha\} = (-1)^{pq+qr+rp+1} \{\alpha, \beta, \gamma\}$ and (vii) $(-1)^{pr} \{\alpha, \beta, \gamma\} + (-1)^{qp} \{\beta, \gamma, \alpha\} + (-1)^{rq} \{\gamma, \alpha, \beta\} \equiv 0$.

S. Functional Operations

Let Φ be an operation corresponding to α and γ be the class of f . We put $\Phi_f(\beta) = \{\alpha, \beta, \gamma\}$ and call Φ_f a **functional Φ -operation**. When Φ is a cohomology operation, Φ_f is called a **functional cohomology operation**. Then $\Phi_f(\beta)$ is defined for β satisfying $f^*(\beta) = \Phi(\beta) = 0$, and $\Phi_f(\beta)$ is determined modulo $\text{Im } Sf^* + \text{Im } \Phi$. For $f: S^{n+k} \rightarrow S^n$, $k = 2i(p-1) - 1$, we denote by $H_p(f) \cdot e_{n+k+1} \in H^{n+k+1}(S^{n+k+1}; \mathbb{Z}_p)$ the image of a generator e_n of $H^n(S^n; \mathbb{Z}_p)$ under the functional \mathcal{P}_f^i operation. Then the **Hopf invariant modulo p** (or **mod p Hopf invariant**) $H_p: \pi_{n+k}(S^n) \rightarrow \mathbb{Z}_p$ is obtained (we use Sq^{2i} for $p = 2$). The following statements are equivalent: (i) The mod 2 Hopf invariant is not trivial ($H_2 \neq 0$); (ii) there exists a mapping: $S^{2k+1} \rightarrow S^{k+1}$ of Hopf invariant 1; (iii) S^k is an H -space; (iv) the Whitehead product $[i, i]$ of a generator i of $\pi_k(S^k)$ vanishes. Also, $H_2 \neq 0$ if and only if $k = 2, 4, 8$ (J. Adams), and for an odd prime p , $H_p \neq 0$ if and only if $k = 2p - 3$ (A. L. Liulevicius; N. Shimada and T. Yamanoshita).

T. Stable Homotopy Groups and Spectra

The homotopy set $\pi(S^n X, S^n Y)_0$ for n -fold iterated suspensions $S^n X = X \wedge S^n = SS^{n-1} X$ and $S^n Y$, forms a group (an Abelian group) if $n \geq 1$ ($n \geq 2$). The limit $\pi^*(X; Y) = \lim \pi(S^n X; S^n Y)_0$ with respect to the suspension homomorphisms $S: \pi(S^n X; S^n Y)_0 \rightarrow \pi(S^{n+1} X; S^{n+1} Y)_0$ is called a **stable homotopy group** of X and

Y . For an r -connected space Y and a CW-complex X , $S: \pi(X; Y)_0 \rightarrow \pi(SX; SY)_0$ is bijective if $\dim X \leq 2r$ and surjective if $\dim X \leq 2r + 1$ (**generalized suspension theorem**). Thus, if X is a finite-dimensional CW-complex, $\pi^s(X, Y)$ is isomorphic to $\pi(S^n X, S^n Y)_0$ for sufficiently large n . To discuss stable homotopy groups more generally, the following concept of spectra is used. A system $E = \{E_k, \varepsilon_k\}$ which consists of CW-complexes E_k and continuous mappings $\varepsilon_k: SE_k \rightarrow E_{k+1}$ is called a **spectrum**. When $E_k = S^k$ and $\varepsilon_k = 1_{k+1}: S^k \rightarrow S^{k+1}$, $S = \{S^k, 1_{k+1}\}$ is called a **sphere spectrum**. When $E_k = K(G, k)$ (\dagger Eilenberg-MacLane complex) and ε_k induces a homotopy equivalence $K(G, k) \simeq \Omega K(G, k + 1)$, $HG = \{K(G, k), \varepsilon_k\}$ is called an **Eilenberg-MacLane spectrum**. As in the latter, a spectrum E in which ε_k induces a homotopy equivalence $E_k \simeq \Omega E_{k+1}$ is called an Ω -spectrum. By Bott's periodicity, Ω -spectra $KU = \{Z \times B_\infty, U, Z \times B_\infty, U, \dots\}$ and $KO = \{Z \times B_\infty, U/O, Sp/U, Sp, Z \times B_\infty, U/Sp, SO/U, O, Z \times B_\infty, \dots\}$ are obtained (\rightarrow Section V). Also, using \dagger Thom complexes, **Thom spectra** MU, MO , etc. are obtained. Given a spectrum E , by putting $E^n(X, A) = \lim \pi(S^k(X/A); E_{k+1})_0$ for each pair (X, A) of CW-complexes, we obtain a **generalized cohomology theory with E-coefficient**; and by putting $E_n(X, A) = \lim \pi_k(E_{k-n} \wedge (X/A))$, we obtain a **generalized homology theory with E-coefficient**. \dagger Generalized (co)homology theory on (finite) CW-complexes can be represented by a suitable spectrum (G. W. Whitehead, E. H. Brown, Adams). Corresponding to $E = S, HG, KU, MU$, etc., we have stable (co)homotopy groups, G -coefficient (co)homology groups, K -groups, \dagger (co)bordism groups, etc., respectively (\rightarrow 201 Homology Theory).

U. Homotopy Groups of Spheres

The spheres S^n and their homotopy groups are basic objects in homotopy theory. Although much research has been done concerning these objects, there are still open problems.

S^n is $(n - 1)$ -connected: $\pi_i(S^n) = 0$ ($i < n$). The fact that $\pi_n(S^n) \cong \mathbb{Z}$ (infinite cyclic group) was obtained from the \dagger Brouwer mapping theorem. Also, $\pi_i(S^1) = 0$ ($i > 1$) follows from the fact that the \dagger universal covering space of S^1 is contractible. Suppose that we are given a continuous mapping $f: S^{2n-1} \rightarrow S^n$. We approximate it by a \dagger simplicial mapping φ . Then the inverse image $\varphi^{-1}(\ast)$ of a point \ast in the interior of an n -simplex of S^n is an $(n - 1)$ -dimensional \dagger pseudomanifold which is orientable by means of a suitable generator $\varepsilon \in H_{n-1}(\varphi^{-1}(\ast))$. The boundary isomorphism $\partial: H_n(S^{2n-1}, \varphi^{-1}(\ast)) \cong H_{n-1}(\varphi^{-1}(\ast))$ and the homomorphism $\varphi_\ast:$

$H_n(S^{2n-1}, \varphi^{-1}(\ast)) \rightarrow H_n(S^n, \ast)$ give rise to an integer $\gamma(\varphi)$ determined by the relation $\varphi_\ast \partial^{-1}(\varepsilon) = \gamma(\varphi) \varepsilon_n$ (ε_n is an orientation of S^n). This integer is independent of the choice of φ , so we can set $\gamma(f) = \gamma(\varphi)$. Then $f \simeq g$ implies that $\gamma(f) = \gamma(g)$. We call $\gamma(f)$ the **Hopf invariant** of f . H. Hopf defined γ and showed $\gamma: \pi_3(S^2) \cong \mathbb{Z}$ (1931); $\gamma(\pi_{2n-1}(S^n)) = 0$ for odd n ; $\gamma(\pi_{2n-1}(S^n)) \subset 2\mathbb{Z}$ for even n ; and $\gamma(\pi_{2n-1}(S^n)) = \mathbb{Z}$ for $n = 4, 8$ (1935). H. Freudenthal defined a homomorphism $E: \pi_i(S^n) \rightarrow \pi_{i+1}(S^{n+1})$, $E[f] = [Sf]$, and proved the **Freudenthal theorem**: (1) E is an isomorphism for $i < 2n - 1$; (2) E is a surjection for $i = 2n - 1$; and (3) the image of E coincides with the kernel of γ for $i = 2n$. Furthermore he obtained $\pi_{n+1}(S^n) \cong \mathbb{Z}_2$ ($n \geq 3$) (1937). For $n = 2, 4, 8$, a mapping $f: S^{2n-1} \rightarrow S^n$ (\dagger Hopf mapping) such that $\gamma(f) = 1$ (given by Hopf) is the projection of a \dagger fiber bundle S^{2n-1} over the base space S^n , and the correspondence $(\alpha, \beta) \rightarrow E\alpha + f_\ast \beta$ gives an isomorphism $\pi_{i-1}(S^{n-1}) + \pi_i(S^{2n-1})$ (direct sum) $\cong \pi_i(S^n)$. Hence we obtain $\pi_4(S^2) = \mathbb{Z}_2$. It was shown by G. W. Whitehead and L. S. Pontryagin that $\pi_{n+2}(S^n)$ ($n \geq 3$) is isomorphic to \mathbb{Z}_2 (1949). Whitehead also defined a **generalized Hopf homomorphism** $H: \pi_i(S^n) \rightarrow \pi_i(S^{2n-1})$ for a range of $i < 3n - 3$, and this restriction on the dimension was removed by P. J. Hilton and I. M. James. Using H , many nontrivial results concerning $\pi_i(S^n)$ have been obtained. Serre obtained the following (1951–1953): $\pi_i(S^n)$ is finite except when $i = n$ or $i = 4m - 1$ and $n = 2m$. Furthermore, $\pi_{4m-1}(S^{2m})$ is the direct sum of \mathbb{Z} and a finite group. Let p be an odd prime and n be even. Then $\pi_i(S^n)$ is \mathcal{C}_p -isomorphic to $\pi_{i-1}(S^{n-1}) + \pi_i(S^{2n-1})$. Let n be odd. Then $\pi_{n+k}(S^n) \in \mathcal{C}_p$ ($k < 2p - 3$), and $\pi_{n+2p-3}(S^n)$ is \mathcal{C}_p -isomorphic to \mathbb{Z}_p . Serre and H. Toda determined $\pi_{n+k}(S^n)$ for $k = 3, 4, 5$, and Serre further determined it for $k = 6, 7, 8$. Utilizing the reduced product space of S^n , James gave the sequence

$$\begin{aligned} \dots \rightarrow \pi_i(S^n) \xrightarrow{E} \pi_{i+1}(S^{n+1}) \xrightarrow{H} \pi_{i+1}(S^{2n+1}) \\ \rightarrow \pi_{i-1}(S^n) \rightarrow \dots \end{aligned}$$

and showed that it is an exact sequence if n is odd and an exact sequence mod 2 if n is even (1953). Using this exact sequence and the secondary composition, Toda determined $\pi_{n+k}(S^n)$ for $k \leq 19$ (\rightarrow Appendix A, Table 6.VI).

By the Freudenthal theorem (1), the $\pi_{n+k}(S^n)$ ($n > k + 1$) for a fixed k are isomorphic to each other. We call $\pi_{n+k}(S^n)$ ($n > k + 1$) the **stable homotopy group of the k -stem** of the sphere and denote it by G_k . For $k = 0, 1, 2, \dots, 15, \dots$, $G_k \cong \mathbb{Z}, \mathbb{Z}_2, \mathbb{Z}_2, \mathbb{Z}_{24}, 0, 0, \mathbb{Z}_2, \mathbb{Z}_{240}, \mathbb{Z}_2 + \mathbb{Z}_2, \mathbb{Z}_2 + \mathbb{Z}_2 + \mathbb{Z}_2, \mathbb{Z}_6, \mathbb{Z}_{504}, 0, \mathbb{Z}_3, \mathbb{Z}_2 + \mathbb{Z}_2, \mathbb{Z}_{480} + \mathbb{Z}_2, \dots$. For the computation of G_k , the notion of n -connective fiber spaces is important. By

utilizing the Adams spectral sequence, we can show that G_k is closely related to the cohomology of the \dagger Steenrod algebra. Let p be an odd prime. There exist the following sequences of elements of order p : $\{\alpha_i \in G_k (k = 2i(p-1) - 1)\}$, $\{\beta_i \in G_k (k = 2(ip + i - 1)(p-1) - 2)\}$ and for $p > 3$ $\{\gamma_i \in G_k (k = 2(ip^2 + (i-1)p + i - 2)(p-1) - 3)\}$. The p -component of G_k is determined for $k < 2p^2(p-1) - 3$ by using Steenrod algebra. To compute G_k for higher k , relations such as $\alpha_1 \beta_1^p = 0$, $\beta_i \beta_1^p = 0$ ($i > 1$) are necessary. In general, each element of G_k ($k \neq 0$) is nilpotent (G. Nishida). Let $\pi_i(S^n; p)$ be the p -component of $\pi_i(S^n)$. To survey this group for the nonstable case ($i \geq 2n - 1$), we utilize Serre's mod p direct sum decomposition (for n even), and we have the following two exact sequences for the case of odd n :

$$\begin{aligned} \dots \rightarrow \pi_i(S^n) \xrightarrow{E^2} \pi_{i+2}(S^{n+2}) \rightarrow \pi_i(\Omega^2(S^{n+2}), S^n) \xrightarrow{\circ} \dots, \\ \dots \rightarrow \pi_{i+3}(S^{pn+p+1}; p) \xrightarrow{\Delta} \pi_{i+1}(S^{pn+p-1}; p) \\ \rightarrow \pi_i(\Omega^2(S^{n+2}), S^n; p) \rightarrow \pi_{i+2}(S^{pn+p+1}; p) \xrightarrow{\Delta} \dots, \end{aligned}$$

where $E^2 = E \circ E$ and $\Delta E^2(\alpha) = p\alpha$ (\rightarrow Appendix A, Table 6.VI).

V. Homotopy Groups of Classical Groups

Consider the classical group $U(n, \Lambda)$, which is either the orthogonal group $O(n)$ ($\Lambda = \mathbf{R}$); the unitary group $U(n)$ ($\Lambda = \mathbf{C}$); or the symplectic group $Sp(n)$ ($\Lambda = \mathbf{H}$). The **infinite classical group** $U(\infty, \Lambda)$ is defined to be the inductive limit group of $\{U(n, \Lambda) | n = 1, 2, \dots\}$ with respect to the natural injection $U(n, \Lambda) \subset U(n+1, \Lambda)$. We call $U(\infty, \Lambda)$ the **infinite orthogonal group**, **infinite unitary group**, and **infinite symplectic group** for $\Lambda = \mathbf{R}$, \mathbf{C} , and \mathbf{H} , respectively. The dimensions of the cells of $U(\infty, \Lambda) - U(n, \Lambda)$ are $\geq \lambda(n+1) - 1$, where $\lambda = \dim_{\mathbf{R}} \Lambda$ ($= 1$ ($\Lambda = \mathbf{R}$), $= 2$ ($\Lambda = \mathbf{C}$), $= 4$ ($\Lambda = \mathbf{H}$)). It follows that $\pi_k(U(n, \Lambda))$ is isomorphic to $\pi_k(U(\infty, \Lambda))$ for $k < \lambda(n+1) - 2$, which is called the k th **stable homotopy group of the classical group**. Let $\mathbf{O} = U(\infty, \mathbf{R})$, $\mathbf{U} = U(\infty, \mathbf{C})$, $\mathbf{Sp} = U(\infty, \mathbf{H})$. The homotopy groups of the classical groups are periodic ($k \geq 0$):

$$\begin{aligned} \pi_k(\mathbf{U}) \cong \pi_{k+2}(\mathbf{U}) \cong \mathbf{Z}, \quad k \text{ odd}, \\ \cong 0, \quad k \text{ even}, \\ \pi_k(\mathbf{O}) \cong \pi_{k+4}(\mathbf{Sp}) \cong \pi_{k+8}(\mathbf{O}), \\ \cong \mathbf{Z}, \quad k \equiv 3, 7 \pmod{8}, \\ \cong \mathbf{Z}_2, \quad k \equiv 0, 1 \pmod{8}, \\ \cong 0, \quad k \equiv 0, 1, 3, 7 \pmod{8}. \end{aligned}$$

This is called the **Bott periodicity theorem**. The relations are deduced from weak homotopy equivalences $\mathbf{U} \rightarrow \Omega(B_{\mathbf{U}})$, $B_{\mathbf{U}} \times \mathbf{Z} \rightarrow \Omega(\mathbf{U})$, $B_{\mathbf{O}} \times \mathbf{Z} \rightarrow \Omega(\mathbf{U}/\mathbf{O})$, $\mathbf{U}/\mathbf{O} \rightarrow \Omega(\mathbf{Sp}/\mathbf{U})$, $\mathbf{Sp}/\mathbf{U} \rightarrow \Omega(\mathbf{Sp})$, \mathbf{Sp}

$\rightarrow \Omega(B_{\mathbf{Sp}})$, $B_{\mathbf{Sp}} \times \mathbf{Z} \rightarrow \Omega(\mathbf{U}/\mathbf{Sp})$, $\mathbf{U}/\mathbf{Sp} \rightarrow \Omega(\mathbf{O}/\mathbf{U})$, $\mathbf{O}/\mathbf{U} \rightarrow \Omega(\mathbf{O})$. This result is applied to nonstable cases; for example, $\pi_{2n}(U(n))$ is a cyclic group of order $n!$ (\rightarrow Appendix A, Table 6.VI). The 2-dimensional homotopy group $\pi_2(G)$ of any Lie group is trivial.

Let $\alpha \in \pi_k(O(n))$, where $\alpha = [f]$, $f: S^k \rightarrow O(n)$. We define $\bar{f}: S^k \times S^{n-1} \rightarrow S^{n-1}$ by $\bar{f}(x, y) = f(x) \cdot y$ and identify S^{k+n} with the boundary $(E^{k+1} \times S^{n-1}) \cup (S^k \times E^n)$ of $E^{k+1} \times E^n$. We extend \bar{f} to $f: S^{k+n} \rightarrow S^n$ so that it maps $E^{k+1} \times S^{n-1}$, $S^k \times E^n$ into the upper and lower hemisphere of S^n (S^{n-1} = the equator), respectively. Let $J(\alpha) \in \pi_{n+k}(S^n)$ be the class of the mapping thus obtained. This homomorphism $J: \pi_k(O(n)) \rightarrow \pi_{n+k}(S^n)$ is called a **J -homomorphism** of Hopf and Whitehead. For the stable case, $J: \pi_k(\mathbf{O}) \rightarrow G_k$ is injective for $k \equiv 0, 1 \pmod{8}$, and the order of the image of J is the denominator of $B_{2t}/4t$ (B_{2t} is a \dagger Bernoulli number) or its double for $k = 4t - 1$ (Adams).

203 (III.25) Hopf Algebras

A. General Remarks

The concept of Hopf algebras arose from two directions. First in the field of algebraic topol-

ogy the notion of Hopf algebras arose from the study of homology and cohomology of Lie groups or, more generally, H -spaces. It was introduced by H. Hopf [1], whose basic structure theorem was generalized and applied to several problems by A. Borel [2]. These Hopf algebras are graded as algebras and coalgebras, and they are now used as standard tools in algebraic topology. On the other hand, Hopf algebras without grading were studied in connection with affine algebraic groups and formal groups. The study of nongraded Hopf algebras as an algebraic system was initiated by M. E. Sweedler [3], and many results on Hopf algebras of this type have been applied, not only to the theory of algebraic groups but also to the Galois theory of field extension and to combinatorial theory.

Although these two types of Hopf algebras have similar structures, and the same terminology is used to describe their properties, they are somewhat different from each other. So to avoid confusion in this article, we distinguish between graded Hopf algebras and Hopf algebras.

B. Graded Algebras

A \mathbb{Z} -graded module $A = \sum_{n \geq 0} A_n$ over a field k is said to be of **finite type** when each A_n is finite-dimensional, A is **connected** when an isomorphism $\eta: k \cong A_0$ is given. The \mathbb{Z} -tensor product of two graded modules A and B is a graded module with $A \otimes B = \sum_n (A \otimes B)_n$, $(A \otimes B)_n = \sum_p A_p \otimes B_{n-p}$. We call $A^* = \sum A_n^*$ (where A_n^* is the \mathbb{Z} -dual module of A_n) the **dual graded module** of A . When A and B are of finite type, $A \otimes B$ and A^* are also of finite type, and we have $(A \otimes B)^* = A^* \otimes B^*$ and $A^{**} = A$. When A and B are connected, A^* and $A \otimes B$ are also connected.

Let A be a graded module. If there exists a degree-preserving linear mapping $\varphi: A \otimes A \rightarrow A$, we call (A, φ) a **graded algebra**, whereas if there exists a degree-preserving linear mapping $\psi: A \rightarrow A \otimes A$, we call (A, ψ) a **graded coalgebra**. We call φ a **multiplication**, and ψ a **comultiplication** (or **diagonal mapping**). Usually we write $\varphi(a \otimes b) = ab$ (the **product** of $a, b \in A$), and call $\psi(a)$ the **coproduct** of a . Multiplication and comultiplication are dual operations. If A is of finite type and (A, φ) is a graded algebra, then (A^*, φ^*) (where φ^* is the dual mapping of φ) is a graded coalgebra, and vice versa. A multiplication φ is called **associative** (**commutative**) if $\varphi(1 \otimes \varphi) = \varphi(\varphi \otimes 1)$ ($\varphi \circ T = \varphi$), where $T: A \otimes A \rightarrow A \otimes A$ is the mapping defined by $T(a \otimes b) = (-1)^{pq} b \otimes a$ for $a \in A_p$ and $b \in A_q$. Associativity and commutativity of a comultiplication are defined dually. Let (A, ψ) be a

graded connected coalgebra of finite type, and identify k with A_0 via η . Then the graded algebra (A^*, ψ^*) has the unity of k as unity if and only if ψ satisfies $\psi(1) = 1 \otimes 1$ and $\psi(x) = 1 \otimes x + x \otimes 1 + \sum_i x'_i \otimes x''_i$ ($0 < \deg x'_i < \deg x$) for $\deg x > 0$. In this case we say that ψ has the unity of k as **counity**. For graded algebras (A, φ) and (B, φ') , if $\varphi'' = (\varphi \otimes \varphi') \circ (1 \otimes T \otimes 1): A \otimes B \otimes A \otimes B \rightarrow A \otimes B$, then $(A \otimes B, \varphi'')$ is also a graded algebra, which we denote by $(A \otimes B, \varphi'') = (A, \varphi) \otimes (B, \varphi')$. The tensor product of graded coalgebras is defined as the dual notion of $(A, \varphi) \otimes (B, \varphi')$.

C. Graded Hopf Algebras

For simplicity we assume that graded modules are defined over a field, connected, and of finite type. Let a graded module A be equipped with a multiplication φ and a comultiplication ψ . If φ and ψ have the unity of k as unity and $\psi: (A, \varphi) \rightarrow (A, \varphi) \otimes (A, \varphi)$ is an algebra homomorphism, then we call (A, φ, ψ) a **graded Hopf algebra**. The last condition for a graded Hopf algebra is satisfied if and only if $\varphi: (A, \psi) \otimes (A, \psi) \rightarrow (A, \psi)$ is a homomorphism of graded coalgebras. The dual (A^*, ψ^*, φ^*) is also a graded Hopf algebra, called the **dual Hopf algebra** of (A, φ, ψ) .

D. H -Spaces

Let X be a topological space. The \mathbb{Z} -cohomology group $H^*(X)$ (\mathbb{Z} -homology group $H_*(X)$) considered over a field k has a multiplication d^* (comultiplication d_*), which is induced by the diagonal mapping $d: X \rightarrow X \times X$ and becomes a commutative and associative graded algebra (coalgebra). The groups $H^*(X)$ and $H_*(X)$ are dual to each other (\rightarrow 201 Homology Theory I, J). When X is equipped with a base point x_0 and a base point-preserving continuous mapping $h: X \times X \rightarrow X$ such that $h \circ \iota_i \simeq 1_X$ (\mathbb{Z} -homotopic) for $i = 1$ and 2 (where $\iota_1(x) = (x, x_0)$ and $\iota_2(x) = (x_0, x)$), we call (X, h) an **H -space**, h a **multiplication**, and x_0 a **homotopy identity** of X . Then h induces, through a \mathbb{Z} -K nneth isomorphism, a comultiplication $h^*: H^*(X) \rightarrow H^*(X) \otimes H^*(X)$ (**Hopf comultiplication**) and a multiplication $h_*: H_*(X) \otimes H_*(X) \rightarrow H_*(X)$ (**Pontryagin multiplication**). Then $h^*(\alpha)$ ($\alpha \in H^*(X)$) is called the **Hopf coproduct** of α , and $h_*(\beta \otimes \gamma)$ ($\beta, \gamma \in H_*(X)$) is called the **Pontryagin product** of β and γ . When X is \mathbb{Z} -arcwise connected and $H_*(X)$ is of finite type, $(H^*(X), d^*, h^*)$ and $(H_*(X), h_*, d_*)$ are graded Hopf algebras dual to each other. In particular, when h is **homotopy associative**, i.e., $h \circ (h \times 1_X) \simeq h \circ (1_X \times h)$ (**homotopy commutative**, i.e., $h \simeq h \circ T$, where

$T(x_1, x_2) = (x_2, x_1)$ for $x_i \in X$), then h^* and h_* are associative (commutative). $^* \text{Topological groups and } ^* \text{loop spaces are homotopy associative } H\text{-spaces. If a continuous mapping } g: X \rightarrow X \text{ satisfies } h \circ (1_X \times g) \cong h \circ (g \times 1_X) \cong c \text{ (constant mapping } X \rightarrow \{x_0\}), \text{ then } g \text{ is called a homotopy inverse for } X, h.$

Suppose that a graded Hopf algebra A is defined over a field k of characteristic p and equipped with associative and commutative multiplication, and A is generated by a single element $a \in A_n$. Then A is a $^* \text{polynomial ring } k[a]$ (n is even when $p \neq 2$) or a $^* \text{quotient ring } k[a]/(a^2)$ (n is odd when $p \neq 2$) or $k[a]/(a^{p^f})$ (only when $p \neq 0$; n is even when $p \neq 2$). These are called **elementary Hopf algebras**. Every graded Hopf algebra over a $^* \text{perfect field } k \text{ with associative and commutative multiplication is isomorphic (as a graded algebra) to a tensor product of elementary Hopf algebras (Borel's theorem) [2]. In particular, the cohomology algebra over a field of characteristic 0 of a } ^* \text{compact connected Lie group is isomorphic to a } ^* \text{Grassmann algebra generated by elements of odd degrees [1].$

E. Steenrod Algebras

The $^* \text{Steenrod algebra } \mathcal{A}_p \text{ over } \mathbf{Z}_p \text{ is generated by } ^* \text{Steenrod operations } Sq^i \text{ } (p=2), \mathcal{P}^i \text{ } (p>2), \text{ and the } ^* \text{Bockstein operation } \Delta_p \text{ } (p>2), \text{ with composition of operations defined as multiplication. Then } \mathcal{A}_p \text{ is a connected associative graded algebra of finite type (not commutative). Defining a comultiplication } \psi \text{ of } \mathcal{A}_p \text{ by } \psi(Sq^n) = \sum Sq^i \otimes Sq^{n-i}, \psi(\mathcal{P}^n) = \sum \mathcal{P}^i \otimes \mathcal{P}^{n-i}, \text{ and } \psi(\Delta_p) = 1 \otimes \Delta_p + \Delta_p \otimes 1, \mathcal{A}_p \text{ becomes a graded Hopf algebra with an associative and commutative comultiplication. Thus its dual } \mathcal{A}_p^* \text{ is a graded Hopf algebra with an associative and commutative multiplication, and we can apply Borel's theorem to } \mathcal{A}_p^* \text{ in order to investigate the structure of } \mathcal{A}_p \text{ [4].}$

Let (A, φ, ψ) be a graded Hopf algebra with associative multiplication and comultiplication. Putting $c(1) = 1$ and $c(a) = -a - \sum a'_i \cdot c(a''_i)$ for $\deg a > 0$ (where $\psi(a) = 1 \otimes a + a \otimes 1 + \sum a'_i \otimes a''_i$), we obtain a linear mapping $c: A \rightarrow A$ satisfying $c\varphi = \varphi(c \otimes c)T$. We call c the **conjugation mapping** of A . When the multiplication or comultiplication is commutative, we obtain the relation $c^2 = 1$, and c is a bijection. The conjugation mapping is utilized in studying Steenrod algebras [4, 5].

F. Coalgebras

Now we turn to nongraded cases. Let A be a vector space over a field k , and let $\mu: A \otimes_k A \rightarrow A$ and $\eta: k \rightarrow A$ be linear mappings. Then the

triple (A, μ, η) is said to be an **algebra** over k if $\mu \circ (\mu \otimes 1_A) = \mu \circ (1_A \otimes \mu)$ and $\mu \circ (1_A \otimes \eta) = \mu \circ (\eta \otimes 1_A) = 1_A$, where 1_A is the identity mapping of A , and $A \otimes_k k$ and $k \otimes_k A$ are identified naturally with A . We call μ the **multiplication** and η the **unit mapping** of the algebra. Dually a triple (C, Δ, ε) with C a vector space over k , linear mappings $\Delta: C \rightarrow C \otimes_k C$, and $\varepsilon: C \rightarrow k$ is said to be a **coalgebra** over k if $(1_C \otimes \Delta) \circ \Delta = (\Delta \otimes 1_C) \circ \Delta$ and $(1_C \otimes \varepsilon) \circ \Delta = (\varepsilon \otimes 1_C) \circ \Delta = 1_C$. We call Δ the **comultiplication** or the **diagonal mapping** and ε the **augmentation** or the **counit** of the coalgebra.

An algebra (A, μ, η) is called **commutative** if $\mu \circ T = \mu$, where T is the twist mapping $a \otimes b \mapsto b \otimes a$. A **cocommutative coalgebra** is defined dually. Definitions of the tensor product of two algebras or coalgebras are similar to the definitions in the graded case. If D is a subspace of a coalgebra (C, Δ, ε) over k satisfying $\Delta(D) \subset D \otimes_k D$, then $(D, \Delta|_D, \varepsilon|_D)$ is a coalgebra and is said to be a **subcoalgebra** of C . A subspace I of a coalgebra (C, Δ, ε) over k is called a **coideal** of C if $\Delta(I) \subset C \otimes_k I + I \otimes_k C$ and $\varepsilon(I) = 0$. Then the quotient space C/I has a coalgebra structure induced naturally from (C, Δ, ε) and is said to be a **quotient coalgebra** of C . The intersection and the sum of subcoalgebras of C are again subcoalgebras of C . If S is a subset of C , then the intersection of all subcoalgebras containing S is said to be the subcoalgebra generated by S . The subcoalgebra generated by any finite set or finite-dimensional subspace of C is finite-dimensional.

If (C, Δ, ε) is a coalgebra over k , then the dual space C^* of C has an algebra structure over k with multiplication μ and unit mapping η defined naturally from the $^* \text{dual mappings of } \Delta \text{ and } \varepsilon \text{ respectively. } (C^*, \mu, \eta) \text{ is called the dual algebra of } (C, \Delta, \varepsilon). \text{ Suppose that } (A, \mu, \eta) \text{ is an algebra over } k, \text{ and let } A^\circ \text{ be the subset of the dual space } A^* \text{ of } A \text{ consisting of elements } f \text{ whose kernel contains an ideal } I \text{ such that } A/I \text{ is finite-dimensional. Then } (A^\circ, \Delta, \varepsilon) \text{ is a coalgebra over } k, \text{ where } \Delta \text{ and } \varepsilon \text{ are the linear mappings induced from the dual ones of } \mu \text{ and } \eta, \text{ respectively. } (A^\circ, \Delta, \varepsilon) \text{ is called the dual coalgebra of } (A, \mu, \eta). \text{ The } ^* \text{functors } ()^* \text{ and } ()^\circ \text{ are adjoint to one another in the sense that there is a natural bijective correspondence between the set of algebra homomorphisms of } A \text{ to } C^* \text{ and that of coalgebra homomorphisms of } C \text{ to } A^\circ \text{ for any coalgebra } C \text{ and algebra } A, \text{ where coalgebra homomorphisms are defined as the dual notion of } ^* \text{algebra homomorphisms.}$

A nonzero subcoalgebra D of a coalgebra C is called **simple** if D has no nonzero proper subcoalgebras, and the sum of all simple subcoalgebras of C is called the **coradical** of C . If

C coincides with its coradical, then C is said to be **cosemisimple**. If C has only one simple subcoalgebra, then C is called **irreducible**. C is called **pointed** if all simple subcoalgebras of C are 1-dimensional. An element g of a coalgebra (C, Δ, ε) is called **grouplike** if $\Delta(g) = g \otimes g$ and $\varepsilon(g) = 1$. The set $G(C)$ of grouplike elements in C is linearly independent over k .

G. Bialgebras

A system $(H, \mu, \eta, \Delta, \varepsilon)$ with an algebra structure (H, μ, η) and a coalgebra structure (H, Δ, ε) is said to be a **bialgebra** over k if Δ and ε are algebra homomorphisms. This last condition is equivalent to saying that μ and η are coalgebra homomorphisms. If K is a subspace of a bialgebra $(H, \mu, \eta, \Delta, \varepsilon)$ which is simultaneously a subalgebra and a subcoalgebra of H , then we call K a **subbialgebra** of H . An ideal I of (H, μ, η) which is also a coideal of (H, Δ, ε) is called a **biideal** of H and the quotient space H/I has a bialgebra structure which is said to be a **quotient bialgebra** of H . A linear mapping between bialgebras is a **bialgebra homomorphism** if it is simultaneously an algebra homomorphism and a coalgebra homomorphism. A bialgebra $(H, \mu, \eta, \Delta, \varepsilon)$ is called commutative (cocommutative) if (H, μ, η) ((H, Δ, ε)) is commutative (cocommutative).

Examples. Let kG be the vector space with a set G as free basis over a field k . If we define linear mappings $\Delta: kG \rightarrow G \otimes_k kG$ by $\Delta(x) = x \otimes x$ and $\varepsilon: kG \rightarrow k$ by $\varepsilon(x) = 1$ for x in G , then $(kG, \Delta, \varepsilon)$ is a cocommutative coalgebra over k such that the set $G(kG)$ of grouplike elements is equal to G . Moreover if G is a \dagger semigroup with unit element, then $(kG, \mu, \eta, \Delta, \varepsilon)$ is a cocommutative bialgebra over k , where $\mu(\eta)$ is the multiplication (unit mapping) of the \dagger semigroup algebra kG . This bialgebra is called a **semigroup bialgebra** over k . If L is a \dagger Lie algebra over k and $U(L)$ the \dagger universal enveloping algebra of L with multiplication μ and unit mapping η , then Lie algebra homomorphisms $x \rightarrow x \oplus x$ ($L \rightarrow L \oplus L$) and $x \rightarrow 0$ ($L \rightarrow \{0\}$) induce algebra homomorphisms $\Delta: U(L) \rightarrow U(L \oplus L) \cong U(L) \otimes U(L)$ and $\varepsilon: U(L) \rightarrow k$, respectively. Then $(U(L), \mu, \eta, \Delta, \varepsilon)$ is a cocommutative bialgebra over k , called the **universal enveloping bialgebra** of L .

H. Hopf Algebras

Let (A, μ, η) be an algebra over k and (C, Δ, ε) a coalgebra over k . If f and g are in $R = \text{Hom}_k(C, A)$, then $f * g = \mu \circ (f \otimes g) \circ \Delta$ is called the **convolution** of f and g . Defining $\mu': R \otimes_k R \rightarrow R$ and $\eta': k \rightarrow R$ by $\mu'(f \otimes g) = f * g$

and $\eta'(\alpha) = \alpha \eta \circ \varepsilon$, then (R, μ', η') is an algebra over k . If H is a bialgebra over k with underlying coalgebra H^c and algebra H^A , then $R_H = \text{Hom}_k(H^c, H^A)$ is an algebra over k in the same manner as above. If the identity mapping 1_H of H has the inverse S in R_H under the multiplication μ' , then H is said to be a **Hopf algebra** over k with **antipode** S . Then S satisfies the following: $S(gh) = S(h)S(g)$ for g, h in H , $S \circ \eta = \eta$, $\varepsilon \circ S = \varepsilon$ and $T \circ (S \otimes S) \circ \Delta = \Delta \circ S$, where T is the twist mapping $a \otimes b \rightarrow b \otimes a$. If H is commutative or cocommutative, then $S \circ S = 1_H$.

If H' is another Hopf algebra over k with antipode S' , then a bialgebra homomorphism f of H to H' such that $S'f = fS$ is called a **Hopf algebra homomorphism**. If H and H' are both commutative (cocommutative), then any bialgebra homomorphism of H to H' is a Hopf algebra homomorphism. The \dagger category whose objects are commutative and cocommutative Hopf algebras over a field k and whose morphisms are Hopf algebra homomorphisms is an \dagger Abelian category (A. Grothendieck). If H is a commutative Hopf algebra over a field of characteristic zero, then the underlying algebra H^A has no \dagger nilpotent elements (P. Cartier).

If G is a \dagger group, then the group bialgebra kG given above has an antipode S defined by $S(x) = x^{-1}$ for x in G , and hence kG is a cocommutative Hopf algebra over k . Another example of Hopf algebras is the \dagger coordinate ring of an \dagger algebraic group defined over k . More generally, let $X = \text{Spec}(A)$ be an \dagger affine group scheme over k . Then algebra homomorphisms $\Delta: A \rightarrow A \otimes_k A$, $\varepsilon: A \rightarrow k$, and $S: A \rightarrow A$ are naturally induced from the group structure of X , and $(A, \mu, \eta, \Delta, \varepsilon, S)$ is a commutative Hopf algebra over k , where μ and η are the multiplication and unit mapping of A , respectively. Conversely, if $(A, \mu, \eta, \Delta, \varepsilon, S)$ is a commutative Hopf algebra over k , then $X = \text{Spec}(A)$ is an affine group scheme over k with the group structure induced from Δ, ε , and S . Hence a commutative Hopf algebra over k is nothing but a cogroup object of the category of commutative algebras over k (i.e., a \dagger group object of the \dagger dual category). Dually a cocommutative Hopf algebra over k is nothing but a group object of the category of cocommutative coalgebras over k .

I. Hyperalgebras

If (C, Δ, ε) is a pointed irreducible coalgebra over k , then C contains a unique grouplike element g , and kg is the unique simple subcoalgebra of C . An element a of C satisfying $\Delta(a) = a \otimes g + g \otimes a$ is called **primitive**. The set $P(C)$ of primitive elements in C is a vector

subspace of C . A cocommutative coalgebra C is called **colocal** if C is irreducible, i.e., if the dual algebra C^* of C is a \dagger quasilocal ring. The \dagger dimension of $P(C)$ of a colocal pointed coalgebra C is finite if and only if the dual algebra C^* of C is a \dagger Noetherian complete local ring. A bialgebra $(H, \mu, \eta, \Delta, \epsilon)$ over k is said to be a **hyperalgebra** over k if the underlying coalgebra is colocal. Then the unique simple subcoalgebra (grouplike element) of H is $\eta(k)(\eta(1))$, and $P(H)$ has a Lie algebra structure defined by $[x, y] = xy - yx$ for x, y in $P(H)$.

The universal enveloping bialgebra $U(L)$ of a Lie algebra L over k is a hyperalgebra over k such that the set $P(U(L))$ of primitive elements in $U(L)$ is equal to L . Conversely, if the characteristic of k is zero, any hyperalgebra H over k is isomorphic to the universal enveloping algebra $U(P(H))$ of the Lie algebra $P(H)$. But in positive-characteristic cases $U(P(H))$ is generally a proper subbialgebra of H . Another important example of hyperalgebras is the dual coalgebra $hy(X) = A^\circ$ of the \dagger stalk A at the neutral point of the \dagger structure sheaf of an \dagger algebraic group scheme X over k . In addition, $hy(X)$ has an algebra structure defined from the group structure of X and is a hyperalgebra over k such that $P(hy(X))$ is equal to the Lie algebra $L(X)$ of X . Although $L(X)$ plays an important role in the infinitesimal theory of algebraic groups over a field of characteristic zero, it does not give any information on infinitesimals of orders higher than p in the case of positive characteristic p . In the case of characteristic zero we see $hy(X) = U(L(X))$ and $L(X) = P(hy(X))$, and so $hy(X)$ is a natural substitute for $L(X)$ in positive-characteristic cases. From this viewpoint many interesting results on $hy(X)$ of an algebraic group scheme X which are parallel to those on $L(X)$ in the case of characteristic zero have been obtained [6–8].

204 (XX.10) Hydrodynamical Equations

A. General Remarks

Mathematical analysis of the motion of fluids (\rightarrow 205 Hydrodynamics) gives rise to various kinds of mathematical problems; the equations that govern flows are amongst the most important and most extensively studied of the nonlinear partial differential equations. Here we review only basic and noteworthy results. Sections B–E are concerned with incompressible fluids, while Sections F and G deal with compressible fluids.

B. Nonstationary Solutions of the Navier-Stokes Equation

Let Ω be a bounded domain in \mathbf{R}^m ($m = 2$ or 3) occupied by a fluid, with smooth boundary $\partial\Omega$. If the fluid is viscous and incompressible, its motion can be described by means of the velocity $u = u(t, x)$ and the pressure $p = p(t, x)$ with $t \geq 0$ and $x \in \Omega$ the time variable and the space variable, respectively. For simplicity, we assume that external forces are absent. Then u and p satisfy the **Navier-Stokes equation**

$$\frac{\partial u}{\partial t} + (u \nabla)u = \nu \Delta u - \nabla p, \quad (1)$$

and the **equation of continuity**

$$\operatorname{div} u = 0, \quad (2)$$

where the positive constant ν stands for the (kinetic) viscosity. On $\partial\Omega$, u is subject to the boundary condition

$$u|_{\partial\Omega} = \beta(t, x). \quad (3)$$

The initial value of u is also prescribed:

$$u|_{t=0} = u_0(x). \quad (4)$$

If Ω is unbounded, e.g., if Ω is an exterior domain outside compact surfaces, then

$$u(t, x) \rightarrow U_0(t) \quad (|x| \rightarrow \infty) \quad (3')$$

is imposed in addition as the boundary condition at infinity.

The problem of finding u and p that satisfy (1)–(4) for given β and u_0 is called the **Navier-Stokes initial value problem** (abbreviation, NS initial value problem). Pioneering mathematical studies of this problem were initiated by J. Leray, and since the 1950s various contributions have been made by many authors, including E. Hopf, O. A. Ladyzhenskaya, H. Fujita, T. Kato, and S. Ito (\rightarrow [13, 17, 21]). We state here the result in terms of regular (classical) solutions under the simplifying assumption that Ω is bounded, $\beta \equiv 0$, and u_0 is solenoidal ($\operatorname{div} u_0 = 0$) and smooth. The situation depends nontrivially upon the dimension m . Namely, if $m = 2$, then a regular solution of the NS initial value problem exists uniquely and globally, i.e., for all time. If $m = 3$, we can prove only a local existence theorem (i.e., one holding in a finite interval) of a regular solution. This solution is unique in the interval of its existence; however, it can be extended over the whole interval when the Reynolds number is sufficiently small. In other words, the question of well-posedness of the 3-dimensional NS initial value problem is open at present.

C. Weak and Strong Solutions of the Navier-Stokes Equation

In 1951 Hopf introduced the notion of **weak solutions** of the NS initial value problem and succeeded in proving their global existence (without uniqueness). We here give the definition of **Hopf's weak solution**: Let $C_{0,\sigma}^\infty$ be the set of vector functions $u \in C_{0,\sigma}^\infty(\Omega)$ with $\operatorname{div} u = 0$. By H we denote the closure of $C_{0,\sigma}^\infty$ under the L^2 -norm, and by V the closure of $C_{0,\sigma}^\infty$ under the $W_2^1(\Omega)$ -norm (or equivalently, the Dirichlet norm for bounded Ω). Then an H -valued function $u = u(t)$ is a weak solution of the NS initial value problem with $\beta \equiv 0$ in $[0, T)$ ($0 < T \leq +\infty$) if

(i) $u \in L^\infty(0, T; H) \cap L^2(0, \infty; V)$,

(ii) u is weakly continuous from $[0, T)$ to H , and

(iii) u satisfies the weak equation

$$\int_0^T \left\{ (u, \varphi_t)_{L^2(\Omega)} - \nu (\nabla u, \nabla \varphi)_{L^2(\Omega)} + ((u \cdot \nabla) \varphi, u)_{L^2(\Omega)} \right\} dt = -(u_0, \varphi(0))_{L^2(\Omega)} \quad (5)$$

for all $\varphi \in C_0^\infty([0, T) \times \Omega)$ with $\operatorname{div} \varphi = 0$.

Note that the pressure p has been eliminated

in the weak equation. In general, the uniqueness of Hopf's weak solution is not known except for $m = 2$. However, when a regular solution does exist, then the weak solution coincides with it (a.e.), and is unique. Solutions of the NS initial value problem which are stronger than the weak solution to the extent that the uniqueness can be proved have been introduced, for instance, by A. A. Kiselev and Ladyzhenskaya [12] and Fujita and Kato [5]. Actually the existence and uniqueness theorems of the aforementioned regular solutions are proved using existence theorems of such **strong solutions**. Recently, Y. Giga and T. Miyakawa succeeded in generalizing the Fujita-Kato theory from L^2 to L^p , and thus they have shown that if $u_0 \in L^m(\Omega)$ and is solenoidal, a unique strong solution exists at least locally for any m .

Those strong solutions that satisfy uniqueness, and hence are regular solutions of the NS initial value problem, turn out to be smooth for $t > 0$; they are analytic in $t > 0$ and $x \in \Omega$.

D. Stationary Solutions of the Navier-Stokes Equation

If the flow is steady, u and p are solutions of the boundary value problem consisting of (1) with $\partial u / \partial t$ omitted, (2) and (3) with β independent of t (and, in addition, (3') with a constant U_0 if Ω is an exterior domain). The existence of solutions of this boundary value problem for the case of bounded Ω was established by Leray as one of the earliest applications of his fixed-point theorem. For the case of unbounded Ω , Leray's study was completed and extended by R. Finn, H. Fujita, and others to yield theorems on existence, regularity, and asymptotic behavior in the wakes of solutions (\rightarrow [4, 13, 21]). These stationary solutions are unique if the Reynolds number is sufficiently small. On the other hand, under certain circumstances that involve Quette flow, non-uniqueness or bifurcation of stationary solutions for large Reynolds numbers has been positively proved.

E. Euler's Equation

If the fluid is inviscid and incompressible, the Navier-Stokes equation is reduced to Euler's equation

$$\frac{\partial u}{\partial t} + (u \cdot \nabla) u = -\nabla p. \quad (6)$$

Then the boundary condition is replaced by the frictionless boundary condition, which, in

the homogeneous case, takes the form

$$u_n|_{\partial\Omega}=0, \quad (7)$$

where u_n is the normal component of u . Regular solutions of the initial value problem consisting of (6) with (2), (4), and (7) have been proved to exist for all t if $m=2$ and in a finite time if $m=3$ [1, 11].

F. The General Navier-Stokes Equations

If the fluid is compressible, viscous, and heat-conductive, its motion is described in terms of the density ρ , the velocity u , and some thermodynamic quantity, say the absolute temperature θ , and is governed by the following system of equations, sometimes called the **general Navier-Stokes equations**:

$$\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho u) = 0, \quad (8)$$

$$\frac{\partial u}{\partial t} + (u \cdot \nabla)u = \frac{\mu}{\rho} \left(\Delta + \frac{1}{3} \nabla \operatorname{div} \right) u - \frac{1}{\rho} \nabla p, \quad (9)$$

$$\frac{\partial \theta}{\partial t} + (u \cdot \nabla)\theta = \frac{\kappa}{c_v \rho} \Delta \theta + \frac{\theta}{c_v \rho} (\operatorname{div} u) p_\theta + \frac{\Psi}{c_v \rho}. \quad (10)$$

Here the pressure p is regarded as a function of ρ and θ through the equation of state. The viscosity coefficient μ , the coefficient of heat conduction κ , and c_v , the specific heat at constant volume, are positive constants. We have for simplicity assumed that the external force is absent, and that the Stokes condition for viscosity is satisfied. Finally, Ψ is the dissipation function:

$$\Psi = -\frac{2}{3} \mu (\operatorname{div} u)^2 + \frac{\mu}{2} \sum_{i,j=1}^m \left(\frac{\partial}{\partial x_i} u_j + \frac{\partial}{\partial x_j} u_i \right)^2.$$

If Ω is the whole space, then the initial values ρ_0, u_0, θ_0 of ρ, u, θ are given at $t=0$, and we obtain the Cauchy problem for the general Navier-Stokes equation. Mathematical study of this Cauchy problem has become active since J. Nash [19] and N. Itaya [8] proved the existence of unique regular solutions local in time. Following Itaya's argument, A. Tani constructed a unique regular solution local in time for the initial boundary value problem consisting of (8)–(10) and boundary conditions imposed on u and θ . When it comes to the global existence of solutions, only restricted results are known. The global existence of a regular solution in the 1-dimensional version of the Cauchy problem has been established by Ya. Kanel' [10] and Itaya under certain simplifying assumptions, such that the fluid is a barotropic gas, i.e., one obeying $p = C\rho^\gamma$, where C and $\gamma \geq 1$ are positive constants. The

1-dimensional initial boundary value problem can also be solved globally if the gas is ideal and polytropic, i.e., one for which $p = R\rho\theta$, and with the internal energy proportional to θ and [9]. For the 3-dimensional case, we can only refer to [18], where existence of global solutions of the Cauchy problem has been proved for initial data close to constants under the assumption that the gas is ideal and polytropic.

G. Equations for Inviscid Ideal Gases

When the gas under consideration is inviscid, ideal, and barotropic, we put $\mu=0$ and $p = C\rho^\gamma$ in (9). The equation thus obtained is combined with (8) to yield the following quasilinear hyperbolic system, which admits conservation laws:

$$\begin{aligned} \frac{\partial \rho}{\partial t} + \operatorname{div}(\rho u) &= 0, \\ \frac{\partial u}{\partial t} + (u \cdot \nabla)u + \frac{C}{\rho} \nabla \rho^\gamma &= 0. \end{aligned} \quad (11)$$

If the initial data ρ_0 and u_0 are smooth to some extent, then the Cauchy problem for (11) has a regular solution local in time. Generally, we cannot expect existence of regular solutions global in time, namely, discontinuity is likely to take place in a finite time, which corresponds to the occurrence of shock waves. Therefore we have to introduce weak solutions that admit discontinuity. By definition a piecewise continuous function $\{\rho, u\}$ is a weak solution of (11) if it satisfies (11) in the distribution sense and if its discontinuity is subject to a certain jump condition, called the **Rankine-Hugoniot relation** as well as another condition, called the **entropy condition**, which two conditions allow us to distinguish a physically realizable solution among many possible discontinuous solutions [3, 14]. Global existence of the weak solution has been proved so far only for the 1-dimensional problem with initial data close to constants in the sense that their oscillations and total variations are sufficiently small. Actually in this case we can apply J. Glimm's method [6] to construct weak solutions by means of a difference approximation which involves random numbers. Little is known regarding the uniqueness of weak solutions. Finally, if we are concerned with steady-state solutions of an inviscid compressible fluid and assume that the flow is irrotational, then we are led to a quasilinear partial differential equation of mixed type for the velocity potential Φ , which is elliptic in the subsonic region and hyperbolic in the supersonic region. Classical results concerning these equations may be found in [2, 3].

205 (XX.9) Hydrodynamics

A. General Remarks

Gases and liquids are easily deformed, and they share many kinetic properties. They are examples of fluids. By definition, a **fluid** is a continuous substance having the property that when it is not moving, any part of the substance separated from the rest by a surface exerts an outward force that is perpendicular to the given surface.

Hydrodynamics (or **fluid dynamics**) is concerned with the equilibrium and the motion of gases and liquids without considering their molecular structure. In particular, the branch of the theory concerning fluids in equilibrium is called **hydrostatics**, and **hydrodynamics** sometimes refers to the branch concerning fluids in motion.

There are two methods of describing the motion of a fluid. One regards a fluid as a system consisting of an infinite number of particles and discusses the motion of each particle as a function of time. This is **Lagrange's method**. For example, suppose that a fluid particle with the coordinates $(x, y, z) = (a, b, c)$ at the moment $t = 0$ has coordinates $x = f_1(a, b, c, t)$, $y = f_2(a, b, c, t)$, $z = f_3(a, b, c, t)$ at an arbitrary time t . Then the motion of the fluid is perfectly determined by the functions f_1 , f_2 , and f_3 .

The other is **Euler's method**, which discusses the values of the velocity $\mathbf{v}(u, v, w)$, the density ρ , the pressure p , etc., of the fluid at arbitrary times and positions. From this standpoint each quantity of the fluid is regarded as a function of a space-time point (x, y, z, t) .

The rate at which any physical quantity F varies while moving with the fluid particle is

the **Lagrangian derivative** DF/Dt , which is related to the ordinary partial derivatives by

$$\frac{DF}{Dt} = \frac{\partial F}{\partial t} + u \frac{\partial F}{\partial x} + v \frac{\partial F}{\partial y} + w \frac{\partial F}{\partial z}.$$

The three components (u, v, w) and the two state quantities (p, ρ) (in general, other state quantities, for example, the temperature T and the entropy S , are assumed to be determined by equations of state such as $T = T(p, \rho)$, $S = S(p, \rho)$) are determined by five ($= 1 + 3 + 1$) relations derived from the conservation laws of mass, momentum, and energy, namely, the **equation of continuity**, which corresponds to the conservation of mass,

$$\partial \rho / \partial t + \operatorname{div}(\rho \mathbf{v}) = 0; \quad (1)$$

the **equation of motion**, which corresponds to the conservation of momentum,

$$\partial(\rho \mathbf{v}) / \partial t + \operatorname{div}(\rho \mathbf{v} \otimes \mathbf{v} - \mathbf{p}) = \rho \mathbf{K}, \quad (2)$$

where \mathbf{K} is the external force per unit mass, \mathbf{p} is the stress tensor, and \otimes denotes the tensor product, while divergence is applied to each row vector, and by virtue of (1), the equation (2) can be expressed component-wise as

$$\begin{aligned} \rho \frac{Du}{Dt} &= \frac{\partial p_{xx}}{\partial x} + \frac{\partial p_{xy}}{\partial y} + \frac{\partial p_{xz}}{\partial z} + \rho K_x, \\ \rho \frac{Dv}{Dt} &= \frac{\partial p_{yx}}{\partial x} + \frac{\partial p_{yy}}{\partial y} + \frac{\partial p_{yz}}{\partial z} + \rho K_y, \\ \rho \frac{Dw}{Dt} &= \frac{\partial p_{zx}}{\partial x} + \frac{\partial p_{zy}}{\partial y} + \frac{\partial p_{zz}}{\partial z} + \rho K_z, \end{aligned} \quad (2')$$

and the **energy equation**, which corresponds to the conservation of energy,

$$\partial(\rho v^2/2 + \rho E) / \partial t + \operatorname{div}(\rho \mathbf{v}(v^2/2 + E) - \mathbf{v} \cdot \mathbf{p} + \mathbf{h}) = \rho \mathbf{v} \cdot \mathbf{K}, \quad (3)$$

or the **equation of entropy production**, which is another expression of (3),

$$\rho T DS/Dt = -\operatorname{div} \mathbf{h} + Q, \quad (3')$$

where E is the internal energy per unit mass, Q the heat generated per unit time and volume, and \mathbf{h} the heat flux. Here \mathbf{K} , p_{ik} , \mathbf{h} , and Q or their relations with other quantities (e.g., $\mathbf{h} = -\kappa \operatorname{grad} T$, where κ is the thermal conductivity) are assumed to be known.

B. Perfect Fluids

When there is a velocity gradient in the flow, a tangential stress appears which tends to make the velocity uniform, so that \mathbf{p} is not a diagonal tensor ($-p \delta_{ik}$, i.e., pressure). This property is called fluid **viscosity**. Generally, Q and \mathbf{h} do not vanish in this case. However, in order to simplify the problem we consider a

nonviscous (sometimes also adiabatic) fluid, which is called a **perfect fluid** and is a good approximation in the large of actual fluids. The motion of a perfect fluid is determined by **Euler's equation of motion**

$$\rho D\mathbf{v}/Dt = -\operatorname{grad} p + \rho \mathbf{K}, \quad (4)$$

which is obtained from (1) and (2) by replacing p_{ik} by the pressure only, and also by the thermodynamic relation $DS/Dt = 0$ obtained from (3') by putting $Q = 0$ and $\mathbf{h} = 0$ or its integral $S = \text{constant}$ in **homentropic flow**, which is governed by the **adiabatic law** $p \propto \rho^\gamma$, where γ denotes the ratio of specific heat at constant pressure to that at constant volume. In particular, for a liquid, the density variation can be neglected. Putting $\rho = \text{constant}$ in (1), we have

$$\operatorname{div} \mathbf{v} = 0, \quad (5)$$

which, in conjunction with (4), determines four unknowns (u, v, w, p) as functions of (x, y, z, t).

A fluid of constant density is called an **incompressible fluid**, and one of variable density a **compressible fluid**. Even though it might seem natural to consider gases as examples of compressible fluids, they can be treated as incompressible fluids if the speed of the flow of the gas $q = |\mathbf{v}|$ is small compared with the velocity $c = \sqrt{dp/d\rho}$ of sound propagating in the gas. We call $q/c = M$ the **Mach number**.

The vector $\boldsymbol{\omega}(\xi, \eta, \zeta)$, which is derived from the velocity vector \mathbf{v} as $\boldsymbol{\omega} = \operatorname{rot} \mathbf{v}$, is called the **vorticity**. A small part of the fluid rotates with angular velocity $\boldsymbol{\omega}/2$. If $\boldsymbol{\omega} = 0$, the flow is called **irrotational**, otherwise **rotational**. The curves $dx:dy:dz = u:v:w$ and $dx:dy:dz = \xi:\eta:\zeta$ are called, respectively, **stream lines** and **vortex lines**. The line integral $\oint_C \mathbf{v} \cdot d\mathbf{s}$ along a closed circuit C is called the **circulation** around C .

In irrotational flow, the velocity is expressed as $\mathbf{v} = \operatorname{grad} \Phi$, where Φ is called a **velocity potential**. When the external force \mathbf{K} has a potential Ω ($\mathbf{K} = -\operatorname{grad} \Omega$) and p is a definite function of ρ , we have the **pressure equation**

$$\frac{\partial \Phi}{\partial t} + \frac{1}{2} q^2 + \int \frac{dp}{\rho} + \Omega = \text{constant},$$

which is valid everywhere in the flow. In a steady flow,

$$\frac{1}{2} q^2 + \int \frac{dp}{\rho} + \Omega = \text{constant} \quad (6)$$

is valid along each stream line or each vortex line; this is called the **Bernoulli theorem**. These two equations correspond to energy integrals of the equation of motion. Furthermore, corresponding to the conservation of angular momentum, we have **Helmholtz's vorticity theorem**: When $\mathbf{K} = -\operatorname{grad} \Omega$ and $p = f(\rho)$, vorticity is neither created nor annihilated in the fluid.

For the irrotational motion of an incompressible fluid, $\nabla^2\Phi=0$ is derived from (5). Hence the problem reduces to the determination of a \dagger harmonic function Φ under appropriate boundary conditions (e.g., for a fixed wall, normal velocity $v_n=\partial\Phi/\partial n=0$). For the 2-dimensional problem a **stream function** Ψ is introduced to satisfy (5) by the relation $u=\partial\Psi/\partial y$, $v=-\partial\Psi/\partial x$. Since the \dagger Cauchy-Riemann equations $\partial\Phi/\partial x=\partial\Psi/\partial y$, $\partial\Phi/\partial y=-\partial\Psi/\partial x$ are valid in this case, $f=\Phi+i\Psi$ is an \dagger analytic function of $z=x+iy$. Therefore the theory of 2-dimensional irrotational motion is essentially equivalent to the theory of complex \dagger analytic functions, and consequently the theory of \dagger conformal mapping is a powerful method in the theory of such fluid motion.

For irrotational steady flow of a compressible fluid in which $\Omega=0$, c is determined from (6) as a function of q . Then (1) and (4) yield a \dagger nonlinear partial differential equation for Φ :

$$\left(1-\frac{u^2}{c^2}\right)\frac{\partial^2\Phi}{\partial x^2}+\left(1-\frac{v^2}{c^2}\right)\frac{\partial^2\Phi}{\partial y^2}+\left(1-\frac{w^2}{c^2}\right)\frac{\partial^2\Phi}{\partial z^2}-2\frac{vw}{c^2}\frac{\partial^2\Phi}{\partial y\partial z}-2\frac{wu}{c^2}\frac{\partial^2\Phi}{\partial z\partial x}-2\frac{uv}{c^2}\frac{\partial^2\Phi}{\partial x\partial y}=0. \quad (7)$$

This equation is \dagger elliptic or \dagger hyperbolic (\rightarrow 326 Partial Differential Equations of Mixed Type) according as M is less than 1 (**subsonic**) or greater than 1 (**supersonic**).

For 2-dimensional flow, we can introduce a stream function Ψ from (1) by $u=\partial\Phi/\partial x=(1/\rho)(\partial\Psi/\partial y)$, $v=\partial\Phi/\partial y=-(1/\rho)(\partial\Psi/\partial x)$. By utilizing the idea of \dagger Legendre transformation, this system of nonlinear equations for Φ and Ψ can be reduced to a system of linear equations in the **hodograph plane** (q, θ):

$$\frac{\partial\Phi}{\partial q}=q\frac{d}{dq}\left(\frac{1}{\rho q}\right)\frac{\partial\Psi}{\partial\theta}=-\frac{1-M^2}{\rho q}\frac{\partial\Psi}{\partial\theta},$$

$$\frac{\partial\Phi}{\partial\theta}=\frac{q}{\rho}\frac{\partial\Psi}{\partial q}$$

($d(\rho q)/dq=\rho(1-M^2)$), where the independent variables q and θ are the magnitude and the inclination of the velocity, respectively. The treatment of 2-dimensional compressible flow on the basis of this system is called the **hodograph method**. For a flow of small M , there is a method of successive approximation (M^2 -**expansion method**) which starts from Laplace's equation, neglecting the terms of $O(M^2)$ in (7). For uniform flow (velocity U in the x -direction) past a thin wing or slender body where v and w are small, we have **thin wing theory** or **slender body theory**, whose first approximation is

$$(1-M^2)\frac{\partial^2\Phi}{\partial x^2}+\frac{\partial^2\Phi}{\partial y^2}+\frac{\partial^2\Phi}{\partial z^2}=0. \quad (8)$$

If $M < 1$ or $M > 1$ (although not too large) a linearization (**Prandtl-Glauert approximation**) is possible by replacing M by the Mach number at infinity $M_\infty=U/c_\infty$. For $M > 1$, (8) has a \dagger characteristic surface, which is the **Mach cone** whose central axis makes an angle $\arcsin c/q = \arcsin 1/M$ with the flow. This can be interpreted also as an envelope produced by spherical sound waves with velocity c from a source drifting with velocity q . For $M \sim 1$, we put $\Phi=c_*x+\varphi$ (c_* is the fluid velocity when $q=c$). Then for an adiabatic gas, (8) is approximated by a partial differential equation of \dagger mixed type:

$$\frac{\partial^2\varphi}{\partial y^2}+\frac{\partial^2\varphi}{\partial z^2}=\frac{\gamma+1}{c_*}\frac{\partial\varphi}{\partial x}\frac{\partial^2\varphi}{\partial x^2}. \quad (9)$$

Such a flow in which both domains $M \gtrless 1$ co-exist is called the **transonic flow**, and exact solutions by the hodograph method are known. However, continuous deceleration from $M > 1$ to $M < 1$ generally tends to be unstable or impossible, and the appearance of a **shock wave**, i.e., a discontinuous surface of state quantities, is not unusual. This can be considered as the \dagger weak solution of (1), (2) (3) for a perfect fluid. In particular, in the coordinate system fixed to the surface, its integrated form can be obtained as follows: $[\rho v_n]=0$, $[p\delta_m+\rho v_i v_n]=0$, $[q^2/2+E+p/\rho]=0$ ($[]$ is the jump of the quantity at the surface, and n is the normal component). Supplemented by the entropy increase, these formulas give relations between the fluid velocity and the state variables at the front and back of the shock. In an ideal gas they are called the **Rankine-Hugoniot relation**. Entropy is not uniform behind a curved shock, and the flow is not irrotational. For a weak shock starting from the tip of a pointed slender body, however, the discontinuity is small and approaches the \dagger characteristic surface of (8), i.e., the **Mach wave** (compressive wave, in this case). Rarefactive Mach waves are found in the supersonic flow of acceleration around a convex surface. Such waves contribute to the drag on an obstacle placed in supersonic flow.

C. Viscous Fluids

A body moving uniformly in a fluid at rest (with velocity less than that of sound) suffers no drag as long as the viscosity of the fluid is negligible and the flow is continuous (**d'Alembert's paradox**). Hence we must take the viscosity into account in order to discuss the creation and annihilation of vortices, the generation and structure of shock waves, and the drag acting on obstacles. For this purpose, we extend **Newton's law** stating that frictional stress is proportional to the velocity gradient

and assume that the stress tensor \mathbf{p} is a linear function of the rate-of-strain tensor \mathbf{e} :

$$\begin{aligned} p_{xx} &= -p + \mu' \operatorname{div} \mathbf{v} + \mu e_{xx} - \frac{2}{3} \mu \operatorname{div} \mathbf{v} \\ &= -p + 2\mu \frac{\partial u}{\partial x} + \left(\mu' - \frac{2}{3} \mu \right) \operatorname{div} \mathbf{v}, \dots, \\ p_{yz} &= \mu e_{yz} = \mu \left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \right), \dots \end{aligned}$$

The proportionality constants μ and μ' are called, respectively, the **coefficients of (shear) viscosity and bulk viscosity**. The bulk viscosity is sometimes neglected (**Stokes's assumption**) in the usual hydrodynamics, and then the mean value of the normal stress components equals the pressure. When a fluid satisfies this linear relation between \mathbf{p} and \mathbf{e} , it is called a **Newtonian fluid**. Otherwise, it is called a **non-Newtonian fluid**. Except for a few cases, such as colloid solutions, fluids can be regarded as Newtonian.

If we take the viscosity into account, the equation of motion of an incompressible fluid becomes

$$\rho D\mathbf{v}/Dt = \rho \mathbf{K} - \operatorname{grad} p + \mu \Delta \mathbf{v}. \quad (10)$$

This is called the **Navier-Stokes equation**. A nondimensional quantity $R = \rho UL/\mu$ formed by representative length L , velocity U , density ρ , and viscosity μ of a flow is called the **Reynolds number**. In order for two flows with geometrically similar boundaries to share similar kinetic properties, their Reynolds numbers must be equal. This is called the **Reynolds law of similarity**.

For small R , we can approximate the equation of motion (10) by replacing the acceleration $D\mathbf{v}/Dt$ by $\partial \mathbf{v}/\partial t$ (**Stokes approximation**) or by $\partial \mathbf{v}/\partial t + U \partial \mathbf{v}/\partial x$ (**Oseen approximation**) for a body placed in the uniform flow of velocity U in the x -direction.

For large R , the flow can be regarded as that of a perfect fluid, since we can neglect $\mu \Delta \mathbf{v}$ as long as the velocity gradient is not too large. In the vicinity of a fixed wall, however, the velocity gradient becomes large, because in a very thin layer the velocity decreases rapidly from the value U of a perfect fluid to zero at the wall. This layer is called the **boundary layer**. For the boundary layer, **Prandtl's boundary layer equation**

$$\begin{aligned} \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} &= \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + \frac{\mu}{\rho} \frac{\partial^2 u}{\partial y^2}, \\ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} &= 0 \end{aligned} \quad (11)$$

is valid, where x and y are the coordinates parallel and perpendicular to the wall, respec-

tively, and U is the velocity outside the boundary layer.

If $\partial U/\partial x < 0$, it sometimes happens that the boundary layer separates from the surface of the body. In this case a vortex is generated in the flow, as large vorticities in the boundary layer are carried into the flow. For a body without separation of the boundary layer, the d'Alembert paradox holds and is no longer a "paradox," and the drag is small. Such bodies are called **streamlined**.

In incompressible flow the new problem arises of the interaction of shock waves with the boundary layer. A rapid increase in pressure due to the shock wave formed on the surface of a body invalidates the assumption of a boundary layer and causes its separation. If the Mach number becomes sufficiently large ($M \gtrsim 5$, **hypersonic flow**), the bow shock approaches the body and interferes with the boundary layer. The generation of heat at the boundary layer (e.g., viscous dissipation in Q) requires the consideration of heat transfer as well as viscosity. In this manner, it becomes necessary to treat a complete system of equations which take into account the energy equation (3) as well as the temperature dependence of κ , μ , and μ' .

D. Laws of Similarity

For such complicated systems, \dagger dimensional analysis is often useful (\rightarrow 116 Dimensional Analysis). As laws of similarity, we can consider not only those like the Reynolds law but also others for bodies which transform similarly by \dagger affine transformations. Corresponding to equation (8), the **Prandtl-Glauert law of similarity** for subsonic flow is famous: The pressure coefficient (nondimensional pressure change) for a thin wing of chord (i.e., the length in the direction of flow) l , span L , and thickness τ is

$$C_p(L, \tau) = \lambda C_{p_0}(\sqrt{1 - M_\infty^2} L, \tau/\sqrt{1 - M_\infty^2} \lambda),$$

when λ is an arbitrary constant and C_{p_0} is C_p for a body of scaled length and thickness placed in an incompressible flow. Corresponding to (9), an extension of the famous **von Kármán transonic similarity** is possible:

$$\begin{aligned} C_p(L, \tau) &= \tau^{2/3}(\gamma + 1)^{-1/3} \\ &\times f(\sqrt{|1 - M_\infty^2|} L, (\gamma + 1)\tau/|1 - M_\infty^2|^{3/2}). \end{aligned}$$

E. Turbulence

For low Reynolds numbers, the flow generally has smooth streamlines. For high Reynolds numbers, however, extremely irregular motion in space and time appears. The former is called

laminar flow, and the latter **turbulent flow** (→ 433 Turbulence and Chaos). The transition from laminar to turbulent flow is considered to be due to the instability of the laminar flow, and this transition has been studied by the method of small oscillations. Recently, nonlinear effects have also been examined. Regarding the internal structure of turbulence, statistical theories originated by T. von Kármán and G. I. Taylor (*Proc. Roy. Soc. London*, 151 (1935)) and A. N. Kolmogorov (*Dokl. Akad. Nauk. SSSR*, 30 (1941)) are of central importance.

F. Water Waves

†Surface waves that occur on the free surface of water (or other liquids) are called **water waves**; their restoring forces are gravity and surface tension. If we consider waves generated on still water (assumed to be inviscid and incompressible) in equilibrium, we can regard the flow field associated with the wave motion as †irrotational by virtue of †Helmholtz's vorticity theorem. Hence the flow velocity can be derived from the †velocity potential Φ which satisfies †Laplace's equation $\Delta\Phi=0$, together with the boundary conditions

$$\frac{D(H+z)}{Dt} = \frac{\partial\Phi}{\partial x} \frac{\partial H}{\partial x} + \frac{\partial\Phi}{\partial y} \frac{\partial H}{\partial y} + \frac{\partial\Phi}{\partial z} = 0$$

at $z = -H(x, y)$, (12)

$$\frac{D(h-z)}{Dt} = \frac{\partial h}{\partial t} + \frac{\partial\Phi}{\partial x} \frac{\partial h}{\partial x} + \frac{\partial\Phi}{\partial y} \frac{\partial h}{\partial y} - \frac{\partial\Phi}{\partial z} = 0$$

at $z = z(x, y, t)$, (13)

$$\frac{\partial\Phi}{\partial t} + \frac{1}{2}(\text{grad } \Phi)^2 + gz = \frac{p_0 - p}{\rho} = \frac{\sigma}{\rho R_m}$$

at $z = h(x, y, t)$, (14)

where the Cartesian coordinates x and y are taken in the undisturbed horizontal free surface, while the positive z -axis is vertically upward. The equations $z = -H(x, y)$ and $z = h(x, y, t)$ denote, respectively, the bottom surface (assumed to be known) and the elevation of the free surface measured from the undisturbed level $z=0$, while g stands for the gravitational acceleration, σ the surface tension, p_0 the atmospheric pressure, and $1/R_m$ the †mean curvature of the disturbed free surface expressed as

$$\frac{1}{R_m} = \left[\left\{ 1 + \left(\frac{\partial h}{\partial x} \right)^2 \right\} \frac{\partial^2 h}{\partial y^2} + \left\{ 1 + \left(\frac{\partial h}{\partial y} \right)^2 \right\} \frac{\partial^2 h}{\partial x^2} - 2 \frac{\partial h}{\partial x} \frac{\partial h}{\partial y} \frac{\partial^2 h}{\partial x \partial y} \right] / \left\{ 1 + \left(\frac{\partial h}{\partial x} \right)^2 + \left(\frac{\partial h}{\partial y} \right)^2 \right\}^{3/2}$$

The conditions (12) and (13) imply, respectively, that the fluid does not cross the bottom and the free surface, while (14) expresses the fact that the difference between atmospheric and fluid pressures at the free surface is equal to the normal force (per unit area) due to the surface tension. Thus the problem is formulated as a nonlinear boundary value problem for Laplace's equation including the unknown boundary $z = h(x, y, t)$.

Let us first consider linear waves for which the wave amplitude of the surface elevation is much smaller than any other characteristic linear dimension such as the wavelength or the water depth H (for simplicity, we assume hereafter $H = \text{constant}$, i.e., a flat horizontal bottom). Linearizing the boundary conditions (12)–(14) with respect to h and $\text{grad } \Phi$, and assuming a sinusoidal wave proportional to $\exp[i(\mathbf{k} \cdot \mathbf{r} - \omega t)]$, $\mathbf{k}(k_x, k_y)$ and ω being respectively the (2-dimensional) †wave number vector and the †angular frequency and $\mathbf{r} = (x, y)$, we obtain the dispersion relation

$$\omega^2 = \left(1 + \frac{\sigma k^2}{\rho g} \right) g k \tanh(kH). \quad (15)$$

In a layer of still water the waves are isotropic in the horizontal plane and the dispersion relation involves only the magnitude k of the wave number vector. It is readily seen from (15) that the water waves are typical †dispersive waves in which the †phase velocity $c_p (= \omega/k)$ depends on the wave number k or the wavelength $\lambda (= 2\pi/k)$. It is also evident from (15) that the quantity $\sigma k^2/(\rho g)$ measures the relative importance of surface tension and gravity. Hence for waves with wavelengths much larger than $\lambda_m = 2\pi\sqrt{\sigma/(\rho g)}$ (~ 1.7 cm for water), the effect of surface tension is negligible, and we have **gravity waves**. Conversely, when $\lambda \ll \lambda_m$, the effect of surface tension becomes dominant, and we have **capillary waves** or **ripples**. When the water depth H is much larger than the wavelength λ , we can approximate (15) by $\omega^2 = gk + \sigma k^3/\rho$, since $\tanh(kH) \sim 1$. We call such waves **deep water waves**. On the other hand, if H is much smaller than the wavelength ($kH \ll 2\pi$), we have **shallow** (or **long**) **water waves** for which (15) can be approximated by $\omega^2 = gHk^2 [1 + \{\sigma/(\rho gH^2) - 1/3\} (kH)^2 + \dots]$ if $\sigma/(\rho gH^2) = O(1)$. In particular, if we neglect $O(kH)^2$, we recover the well-known dispersionless **long gravity waves** whose phase velocity is simply \sqrt{gH} . In all the cases mentioned above, the amplitude function of the velocity potential Φ is proportional to $-i\omega \cosh\{k(z+H)\}/\{k \sinh(kH)\}$, so that the flow velocity due to deep water waves decreases exponentially as one proceeds vertically downward from the free surface. In the

limiting case of long gravity waves, however, the fluid motion is nearly horizontal throughout the fluid layer.

When the wave amplitude becomes larger, nonlinear effects are no longer negligible. For such waves, various †singular perturbation methods provide powerful tools. For example, the basic system of equations for weakly nonlinear (1-dimensional) shallow water waves can be reduced to a simple solvable nonlinear equation called the †Korteweg-de Vries equation, whose solitary wave solution is known as a prototype of solitons (\rightarrow 387 Solitons). Another classical example is a (1-dimensional) deep gravity wave called the **Stokes wave**, which can be obtained as a power series in the **wave steepness** (amplitude \times wave number). The first term of the series is of the form of a linear sinusoidal wave, and the higher-order terms correspond to the higher harmonics, while the angular frequency is shifted from the linear case and depends not only on the wave number but also on the amplitude. Similar singular perturbation methods have also been applied to various kinds of resonant interactions such as nonlinear self-modulation, higher harmonic resonances, and multiwave interactions. Finally it should be mentioned that an exact solution representing a (1-dimensional) deep capillary wave was obtained by G. D. Crapper (*J. Fluid Mech.*, 2 (1957) 532–540; extended later to the case of finite depth by W. Kinnersley, *J. Fluid Mech.*, 77 (1976), 229–241). This is one of the few realistic exact solutions obtained so far; a famous exact solution of Gerstner's trochoidal wave does not satisfy the irrotationality condition.

206 (XIV.5) Hypergeometric Functions

A. Hypergeometric Functions

The †power series

$$F(\alpha, \beta, \gamma; z) = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\beta)} \sum_{n=1}^{\infty} \frac{\Gamma(\alpha+n)\Gamma(\beta+n)}{n!\Gamma(\gamma+n)} z^n$$

in the complex variable z is called the **hypergeometric series** or **Gauss's series**.

It is convergent for any α , β , and γ if $|z| < 1$, and is convergent for $\text{Re}(\alpha + \beta - \gamma) < 0$ if $|z| = 1$. If $z = 1$, its sum is equal to $\Gamma(\gamma)\Gamma(\gamma - \alpha - \beta)/\Gamma(\gamma - \alpha)\Gamma(\gamma - \beta)$ (except when γ is a nonpositive integer). The **hypergeometric functions** are obtained as analytic continuations of the functions determined by hypergeometric series that are single-valued analytic functions defined on the domain obtained from the complex plane by deleting a line connecting branch points $z = 1$ and $z = \infty$ (\rightarrow Appendix A, Table 18.1).

A hypergeometric function is a solution of the differential equation

$$z(1-z)\frac{d^2w}{dz^2} + (\gamma - (\alpha + \beta + 1)z)\frac{dw}{dz} - \alpha\beta w = 0, \quad (1)$$

which is called the **hypergeometric differential equation** or **Gaussian differential equation**. This equation is a differential equation of †Fuchsian type with †regular singular points at 0, 1, and ∞ , whose solutions are expressed, in terms of the † P -function of Riemann, by

$$w = P \left\{ \begin{matrix} 0 & \infty & 1 \\ 0 & \alpha & 0 \\ 1-\gamma & \beta & \gamma-\alpha-\beta \end{matrix} \right\} z.$$

If any one of the values of γ , $\gamma - \alpha - \beta$, or $\alpha - \beta$ is integral, there exists a series containing $\log z$, representing a solution of the differential equation (1) in a neighborhood of the corresponding singular points. When none of the γ , $\gamma - \alpha - \beta$, or $\alpha - \beta$ values is integral, since the linear transformations $z' = z$, $z' = 1/z$, $z' = 1 - z$,

$z' = z/(z-1)$, $z' = (z-1)/z$, $z' = 1/(1-z)$ permute singular points, there exist 24 particular solutions around the singular points. The latter fact was first proved by E. E. Kummer (1836).

There exist various curves C for which the integral

$$w = \int_C u^{\alpha-1} (1-u)^{\gamma-\alpha-1} (1-zu)^{-\beta} du$$

is a solution of (1). Among them we can take the segment $[0, 1]$ when $\operatorname{Re} \alpha > 0$, $\operatorname{Re}(\gamma - \alpha) > 0$. Then the corresponding solution is holomorphic in the interior of the unit circle, and

$$F(\alpha, \beta, \gamma; z) = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\gamma-\alpha)} \times \int_C u^{\alpha-1} (1-u)^{\gamma-\alpha-1} (1-zu)^{-\beta} du.$$

Since the integrand has branch points at 0, 1, and $1/z$, we have the following expression when γ is not an integer:

$$F(\alpha, \beta, \gamma; z) = \frac{1}{(1-e^{2\pi i(\gamma-\alpha)})(1-e^{2\pi iz})} \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\gamma-\alpha)} \times \oint^{(1+, 0+, 1-, 0-)} u^{\alpha} (1-u)^{\gamma-\alpha-1} (1-zu)^{-\beta} du,$$

where $\operatorname{Re} \alpha > 0$, $\operatorname{Re}(\gamma - \alpha) > 0$; whereas if γ is an integer, then

$$F(\alpha, \beta, \gamma; z) = \frac{1}{(1-e^{-2\pi iz})} \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\gamma-\alpha)} \times \oint^{(1+, 0+)} u^{\alpha} (1-u)^{\gamma-\alpha-1} (1-zu)^{-\beta} du,$$

where the contour in the first expression encircles successively each of 1, 0, 1, and 0 once with indicated directions. These expressions can be adopted as a definition of the hypergeometric functions for the general value of z . Other integral expressions are also known (\rightarrow Appendix A, Table 18.I).

B. The Ladder Method

A linear ordinary differential equation of the second order having three regular singular points on the complex sphere is easily transformed into an equation of the form (1). To solve such an equation with a parameter, it is often useful to decompose, in two different ways, the main part of the equation into two factors of the first order, and find a recurrence formula involving the parameter, as we shall see in the following example. This method is called the **ladder method** or **factorization method**.

For example, [†]Legendre's differential

equation

$$L_n[w] \equiv (1-z^2)((1-z^2)w)' + n(n+1)w = 0$$

is decomposed as follows:

$$L_n = S_n \cdot T_n + n^2 = T_{n+1} \cdot S_{n+1} + (n+1)^2,$$

$$T_n = (1-z^2) \frac{d}{dz} + nz, \quad S_n = (1-z^2) \frac{d}{dz} - nz.$$

If w_n is a solution of $L_n[w] = 0$, then multiplying both sides of $S_n \cdot T_n[w_n] + n^2 w_n = 0$ by T_n , we find that $T_n \cdot S_n(T_n[w_n]) + n^2(T_n[w_n]) = 0$, that is, $T_n[w_n]$ is a solution of $L_{n-1}[w] = 0$. Similarly, we see that $S_{n+1}[w_n]$ is a solution of $L_{n+1}[w] = 0$. In this sense, S_n and T_n are called, respectively, the **step-up operator**, or **up-ladder**, and the **step-down operator**, or **down-ladder**, with respect to the parameter n .

The above relation constitutes a recurrence formula for Legendre functions (\rightarrow Appendix A, Table 18.II).

C. Extensions of Hypergeometric Functions

J. Thomas (1870) proposed the series

$$1 + \sum_{n=1}^{\infty} \frac{(\alpha_1)_n (\alpha_2)_n \dots (\alpha_h)_n}{(\beta_1)_n (\beta_2)_n \dots (\beta_h)_n} z^n, \\ (\lambda)_n = \lambda(\lambda+1) \dots (\lambda+n-1)$$

as an extension of the hypergeometric series. The sum of this series satisfies the h th-order differential equation

$$(1-z) \frac{d^h w}{dt^h} + (A_1 - B_1 z) \frac{d^{h-1} w}{dt^{h-1}} \\ + (A_2 - B_2 z) \frac{d^{h-2} w}{dt^{h-2}} + \dots + (A_h - B_h z) w = 0,$$

$$t = \log z.$$

When $h=2$ and $\beta_1=1$, it reduces to the ordinary hypergeometric series. The notation

$${}_p F_q(\alpha_1, \alpha_2, \dots, \alpha_p; \beta_1, \beta_2, \dots, \beta_q; z) \\ = \sum_{n=0}^{\infty} \frac{(\alpha_1)_n (\alpha_2)_n \dots (\alpha_p)_n}{n! (\beta_1)_n (\beta_2)_n \dots (\beta_q)_n} z^n, \quad (2)$$

which is due to L. Pochhammer and modified by E. W. Barnes, is used to denote the extended hypergeometric series, and the function defined by (2) is often called **Barnes's extended hypergeometric function**. For example, Gauss's series in this notation is ${}_2F_1(\alpha, \beta, \gamma; z)$.

Corresponding to Barnes's integral expression for hypergeometric functions, it is known that the integral

$$W(z) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} K(\zeta) H(\zeta) z^{-\zeta} d\zeta,$$

where

$$K(\zeta) = K(\zeta+1)$$

and

$$H(\zeta) = \frac{\Gamma(\zeta + \alpha_1)\Gamma(\zeta + \alpha_2) \dots \Gamma(\zeta + \alpha_h)}{\Gamma(\zeta + 1 + \beta_1)\Gamma(\zeta + 1 + \beta_2) \dots \Gamma(\zeta + 1 + \beta_h)},$$

is a solution of the h th-order differential equation at the beginning of this section. The hypergeometric function expressed by the definite integral

$$\int \zeta^a (\zeta - 1)^b (\zeta - z)^c d\zeta$$

has an obvious formal extension

$$\int (\zeta - a_1)^{b_1} (\zeta - a_2)^{b_2} \dots (\zeta - a_m)^{b_m} (\zeta - z)^c d\zeta.$$

On the other hand, the equation

$$\sum_{v=0}^m \varphi_v(z) \frac{d^v w}{dz^v} = 0,$$

where

$$\varphi_v(z) = \frac{(-1)^{m-1-v}}{(h+m-2) \dots (h+1)h} \times \left(\binom{h+m-v-2}{m-v-1} P_1^{(m-1-v)}(z) + \binom{h+m-v-2}{m-v} P_0^{(m-v)}(z) \right),$$

$$P_0(z) = (z - a_1)(z - a_2) \dots (z - a_m),$$

$$P_1(z) = P_0(z) \left(\frac{\beta_1}{z - a_1} + \frac{\beta_2}{z - a_2} + \dots + \frac{\beta_m}{z - a_m} \right),$$

called the **Tissot-Pochhammer differential equation**, has a solution

$$w(z) = \int_c (\zeta - a_1)^{\beta_1-1} (\zeta - a_2)^{\beta_2-1} \dots \times (\zeta - a_m)^{\beta_m-1} (\zeta - z)^{h+m-2} d\zeta.$$

After Pochhammer (1870), this is sometimes called Pochhammer's generalized hypergeometric function.

As another extension of Gauss's series, H. E. Heine (1846) introduced **Heine's series**:

$$\varphi(a, b, c; q; z) = 1 + \frac{(1-q^a)(1-q^b)}{(1-q)(1-q^c)} q^z + \frac{(1-q^a)(1-q^{a+1})(1-q^b)(1-q^{b+1})}{(1-q)(1-q^2)(1-q^c)(1-q^{c+1})} q^{2z} + \dots$$

Setting $q = 1 + \varepsilon$, $z = (1/\varepsilon) \log x$, and letting $\varepsilon \rightarrow 0$, we obtain Gauss's series as the limit of Heine's series.

D. Hypergeometric Functions of Several Variables

P. Appell (1880) formally extended Gauss's series to the case of two variables and defined

Hypergeometric Functions

four kinds of functions [3]:

$$F_1(\alpha; \beta, \beta'; \gamma; x, y)$$

$$= \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(\alpha)_{m+n} (\beta)_m (\beta')_n}{m! n! (\gamma)_{m+n}} x^m y^n,$$

$$F_2(\alpha; \beta, \beta'; \gamma, \gamma'; x, y)$$

$$= \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(\alpha)_{m+n} (\beta)_m (\beta')_n}{m! n! (\gamma)_m (\gamma')_n} x^m y^n,$$

$$F_3(\alpha, \alpha'; \beta, \beta'; \gamma; x, y)$$

$$= \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(\alpha)_m (\alpha')_n (\beta)_m (\beta')_n}{m! n! (\gamma)_{m+n}} x^m y^n,$$

$$F_4(\alpha; \beta; \gamma, \gamma'; x, y)$$

$$= \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(\alpha)_{m+n} (\beta)_{m+n}}{m! n! (\gamma)_m (\gamma')_n} x^m y^n.$$

They are called **Appell's hypergeometric functions of two variables**. Each satisfies a corresponding system of partial differential equations:

$$F_1 \begin{cases} x(1-x)r + y(1-x)s + (\gamma - cx)p - \beta yq \\ \quad \quad \quad - \alpha \beta z = 0, \\ y(1-y)t + x(1-y)s + (\gamma - c'x)q - \beta' xp \\ \quad \quad \quad - \alpha \beta' z = 0, \\ (x-y)s - \beta' p + \beta q = 0, \end{cases}$$

$$F_2 \begin{cases} x(1-x)r - xys + (\gamma - cx)p - \beta yq - \alpha \beta z = 0, \\ y(1-y)t - xys + (\gamma' - c'y)q - \beta' xp \\ \quad \quad \quad - \alpha \beta' z = 0, \end{cases}$$

$$F_3 \begin{cases} x(1-x)r + ys + (\gamma - cx)p - \alpha \beta z = 0, \\ y(1-y)t + xs + (\gamma - c''y)q - \alpha' \beta' z = 0, \end{cases}$$

$$F_4 \begin{cases} x(1-x)r - y^2 t - 2xys + (\gamma - cx)p - cyq \\ \quad \quad \quad - \alpha \beta z = 0, \\ y(1-y)t - x^2 r - 2xys + (\gamma' - cy)q - cxp \\ \quad \quad \quad - \alpha \beta' z = 0, \end{cases}$$

where

$$c = \alpha + \beta + 1, \quad c' = \alpha + \beta' + 1, \quad c'' = \alpha' + \beta' + 1, \\ p = \partial z / \partial x, \quad q = \partial z / \partial y, \quad r = \partial^2 z / \partial x^2, \\ s = \partial^2 z / \partial x \partial y, \quad t = \partial^2 z / \partial y^2.$$

Appell's hypergeometric functions can also be represented by integrals: for example,

$$F_1 = \frac{\Gamma(\gamma)}{\Gamma(\beta)\Gamma(\beta')\Gamma(\gamma - \beta - \beta')} \iint u^{\beta-1} v^{\beta'-1} \times (1-u-v)^{\gamma-\beta-\beta'-1} (1-ux-vy)^{-\alpha} du dv,$$

$$F_2 = \frac{\Gamma(\gamma)\Gamma(\gamma')}{\Gamma(\beta)\Gamma(\beta')\Gamma(\gamma - \beta)\Gamma(\gamma' - \beta')} \int_0^1 \int_0^1 u^{\beta-1} v^{\beta'-1} \times (1-u)^{\gamma-\beta-1} (1-v)^{\gamma'-\beta'-1} (1-ux-vy)^{-\alpha} du dv,$$

$$F_3 = \frac{\Gamma(\gamma)}{\Gamma(\beta)\Gamma(\beta')\Gamma(\gamma-\beta-\beta')} \iint u^{\beta-1} v^{\beta'-1} \times (1-u-v)^{\gamma-\beta-\beta'-1} (1-ux)^{-\alpha} (1-vy)^{-\alpha'} du dv,$$

where, for F_1 and F_3 , the domain of integration is $u \geq 0, v \geq 0, 1-u-v \geq 0$. E. Picard (1881) showed that F_1 can also be expressed by a single integral:

$$F_1 = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\alpha-\gamma)} \int_0^1 u^{\alpha-1} (1-u)^{\gamma-\alpha-1} \times (1-ux)^{-\beta} (1-uy)^{-\beta'} du.$$

G. Lauricella (1893) extended the foregoing functions to the case of more than two variables. More general hypergeometric series of several variables were defined by R. Mellin, J. Horn, and J. Kampé de Fériet [3, 4]. Every algebraic equation can be solved analytically in terms of the foregoing functions (Mellin, R. Birkeland) [4]. Also there are studies concerning [†]Riemann's problem and [†]automorphic functions derived from F_1 (Picard; T. Terada [5]).

E. Hypergeometric Functions with Matrix Argument

For symmetric matrices Z of degree m , C. S. Herz defined **hypergeometric functions with matrix argument** as follows [5]: Denoting by $\text{etr } Z$ the exponential $\exp(\text{tr } Z)$ of the [†]trace of Z , let

$$\begin{aligned} {}_0F_0(Z) &= \text{etr } Z, \\ {}_{p+1}F_q(\alpha_1, \dots, \alpha_p; \beta_1, \dots, \beta_q; \gamma; Z) \\ &= \frac{1}{\Gamma_m(\gamma)} \int_{\Lambda > 0} \text{etr}(-\Lambda) {}_pF_q(\alpha_1, \dots, \alpha_p; \beta_1, \dots, \beta_q; \\ &\quad \Lambda Z)(\det \Lambda)^{\gamma-p} d\lambda_{11} d\lambda_{22} \dots d\lambda_{mm}, \quad (3) \end{aligned}$$

$$\begin{aligned} {}_pF_{q+1}(\alpha_1, \dots, \alpha_p; \beta_1, \dots, \beta_q; \gamma; \Lambda) \\ &= \frac{\Gamma_m(\gamma)}{(2\pi i)^{m(m+1)/2}} \int_{\text{Re } Z = X_0 > 0} \text{etr } Z {}_pF_q(\alpha_1, \dots, \alpha_p; \\ &\quad \beta_1, \dots, \beta_q; \Lambda Z^{-1})(\det Z)^{-\gamma} dz_{11} dz_{22} \dots dz_{mm}, \quad (4) \end{aligned}$$

where

$$\Lambda = (\lambda_{ij})_{i,j=1,\dots,m},$$

$$Z = ((1 + \delta_{ij})z_{ij}/2)_{i,j=1,\dots,m},$$

$$\Gamma_m(\gamma) = \pi^{m(m-1)/4} \Gamma(\gamma) \Gamma(\gamma - 1/2) \dots$$

$$\times \Gamma(\gamma - (m-1)/2),$$

and $\Lambda > 0$ means that Λ is [†]positive definite. The integral (3) converges for $-Z > 0$ if $\text{Re } \gamma > (m-1)/2$. If $\text{Re } \gamma$ is sufficiently large, then for suitably chosen X_0 , (4) converges in a domain of the space of Λ and represents an analytic function of its argument. In particular, we

have

$${}_1F_0(x; Z) = (\det(E - Z))^{-x}.$$

Based on this definition, many special functions and formulas are extended to the case of a matrix argument. For example,

$$A_\delta(Z) = {}_0F_1(\delta + (m+1)/2; -Z)/\Gamma_m(\delta + (m+1)/2) \quad (5)$$

is an extension of the [†]Bessel function, and this reduces to

$$(t/2)^{-\delta} J_\delta(t) = A_\delta((t/2)^2)$$

when $m = 1$. Formula (5) is applied to the [†]noncentral Wishart distribution in mathematical statistics.

207 (XI.13) Ideal Boundaries

A. Ideal Boundaries

For a given Hausdorff space R , a \dagger compact Hausdorff space R^* that contains R as its dense subspace is called a **compactification** of R , and $\Delta = R^* - R$ is called an **ideal boundary** of R . In the present article, we deal mainly with properties (in particular, function-theoretic properties) of ideal boundaries of \dagger Riemann surfaces R .

B. Harmonic Boundaries

By R we mean an open Riemann surface. The set Γ of points p^* in Δ such that $\liminf_{R \ni p \rightarrow p^*} P(p) = 0$ for every \dagger potential P (i.e., a positive \dagger superharmonic function P for which the class of nonnegative \dagger harmonic functions smaller than P consists only of the constant function 0) is a compact subset of R^* . The set Γ is called the **harmonic boundary** of R with respect to R^* . For an arbitrary compact subset K in $\Delta - \Gamma$, there exists a finite-valued potential P_K with $\lim_{R \ni p \rightarrow p^*} P_K(p) = \infty$ ($p^* \in K$). From this, various kinds of \dagger maximum principles are derived. For instance, if u is a harmonic function bounded above for which $\limsup_{p \rightarrow \Gamma} u(p) \leq M$ holds, then $u \leq M$ on R .

There are infinitely many compactifications of R . For two compactifications R_i^* ($i = 1, 2$) of R , we say that R_1^* is **greater than** R_2^* or, equivalently, **lies over** R_2^* , if the identity mapping of R can be extended to a continuous mapping of R_1^* onto R_2^* . In order that deep function-theoretic studies of R^* can be carried out, various conditions must be imposed on R^* . A compactification R^* is said to be of **Stoilow type** (or of **type S**) if for every \dagger connected open subset G^* in R^* whose boundary in R^* is contained in R , $G^* - \Delta$ is also connected. Next suppose that $R \notin O_G$ (\rightarrow 367 Riemann Surfaces E). For a given real-valued function f on Δ , let \underline{H}_f^{R, R^*} (\underline{H}_f^{R, R^*}) be the class of \dagger superharmonic functions s bounded from below (\dagger subharmonic functions s bounded from above) such that $\liminf_{R \ni p \rightarrow p^*} s(p) \geq f(p^*)$ ($\limsup_{R \ni p \rightarrow p^*} s(p) \leq f(p^*)$) for every $p^* \in \Delta$. If these classes are nonempty, then $\bar{H}_f^{R, R^*}(p) = \inf\{s(p) | s \in \underline{H}_f^{R, R^*}\}$ and $\underline{H}_f^{R, R^*}(p) = \sup\{s(p) | s \in \underline{H}_f^{R, R^*}\}$ are harmonic on R , and $\underline{H}_f^{R, R^*} \leq \bar{H}_f^{R, R^*}$. In particular, if $\underline{H}_f^{R, R^*} \equiv \bar{H}_f^{R, R^*}$, then the common function is denoted by H_f^{R, R^*} , and the function f is said to be **resolutive** with respect to R^* . A compactification such that every bounded continuous function on Δ is resolutive is called a **resolutive compactification**. In

such a case, a point p^* in Δ is said to be **regular** with respect to the \dagger Dirichlet problem if $\lim_{R \ni p \rightarrow p^*} H_f^{R, R^*}(p) = f(p^*)$ for every bounded continuous function f on Δ (\rightarrow 120 Dirichlet Problem). The set Δ_r of regular points in Δ is contained in Γ . If R^* is a resolutive compactification, then there exists a unique positive \dagger Borel measure μ_p such that $H_f^{R, R^*}(p) = \int_{\Delta} f(p^*) d\mu_p(p^*)$ for every bounded continuous function f on Δ . This measure is called the **harmonic measure** with respect to $p \in R$. There exists a function $P(p, p^*)$ on $R \times \Delta$ with $d\mu_p(p^*) = P(p, p^*) d\mu_o(p^*)$ for an arbitrary fixed point o in R satisfying the following three conditions: (i) $P(p, p^*)$ is harmonic on R as a function of p ; (ii) $P(p, p^*)$ is Borel measurable as a function of p^* ; (iii) $k(o, p)^{-1} \leq P(p, p^*) \leq k(o, p)$, with the Harnack constant $k(o, p)$ of $\{o, p\}$ relative to R [9].

C. Compactifications Determined by Function Families

A family F of real-valued continuous functions on R admitting infinite values is called a **separating family** on R if there exists an f in F such that $f(p) \neq f(q)$ for any pair of given distinct points p and q in R . A compactification R^* is called an **F -compactification**, denoted by R_F^* , if every function in F can be continuously extended to R^* and the family of extended functions again constitutes a separating family on R^* . The correspondence $\varphi: F \rightarrow R_F^*$ defines a single-valued mapping of all separating families F on R onto all F -compactifications of R . If $F_1 \supset F_2$, then $\varphi(F_1)$ lies over $\varphi(F_2)$. For any R^* , $\varphi^{-1}(R^*)$ contains infinitely many separating families, among which the separating families constituting \dagger associative algebras are important. The following are typical examples of compactifications determined by function families:

(1) The **Aleksandrov compactification** is the \mathcal{U} -compactification $R_{\mathcal{U}}^*$ with the family \mathcal{U} of bounded continuous functions on R with compact support. It is the smallest compactification of R and is often used in function theory in discussing Dirichlet problems for relatively noncompact subregions in reference to relative boundaries.

(2) The **Stone-Ćech compactification** is the \mathcal{C} -compactification $R_{\mathcal{C}}^*$ with the family \mathcal{C} of bounded continuous functions on R . It is the largest compactification of R . It is rarely used in function theory, but an application is found in the work of M. Nakai [8].

(3) The **Kerékjártó-Stoilow compactification** is the \mathcal{S} -compactification $R_{\mathcal{S}}^*$ with the family \mathcal{S} of bounded continuous functions f on R

such that there exist compact sets K_f with the property that the f are constants on each connected component of $R - K_f$. This is the smallest compactification of Stoilow type. Many applications of this compactification can be found in function theory, among which the investigation done by M. Ohtsuka on the Dirichlet problem and the theory of conformal mappings is typical.

(4) The **Royden compactification** is the \mathfrak{R} -compactification $R_{\mathfrak{R}}^*$ with the family \mathfrak{R} of bounded C^∞ functions f on R with finite Dirichlet integrals $\iint_R df \wedge *df$. It was introduced by H. L. Royden and developed further by S. Mori, M. Ôta, Y. Kusunoki, Nakai, and others. This compactification has been used effectively in the study of HD -functions and the classification problem of Riemann surfaces (\rightarrow 367 Riemann Surfaces).

(5) The **Wiener compactification** is the \mathfrak{W} -compactification $R_{\mathfrak{W}}^*$ with the family \mathfrak{W} of bounded continuous functions f on R such that $\{H_f^{G_n}\}$ converges to a unique harmonic function independent of the choice of exhaustions $\{G_n\}$ of an arbitrary fixed subregion $G \notin O_G$, where the G_n are relatively compact subregions of G . It is the largest resolutive compactification, and compactifications smaller than $R_{\mathfrak{W}}^*$ are always resolutive. This compactification was introduced independently by Mori, K. Hayashi, Kusunoki, and C. Constantinescu and A. Cornea and is useful for the study of HB -functions and the classification of Riemann surfaces.

(6) The **Martin compactification** is the \mathfrak{M} -compactification $R_{\mathfrak{M}}^*$ with the family \mathfrak{M} of bounded continuous functions f on R such that there exist relatively compact regions R_f with the property that $f = H_{f^*}^{R - R_f, R_{\mathfrak{M}}^* - R_f} / H_{1^*}^{R - R_f, R_{\mathfrak{M}}^* - R_f}$ on $R - R_f$. Here f^* coincides with f on R_f and equals 0 on $R_{\mathfrak{M}}^* - R$, and 1^* is similarly defined. The set $R_{\mathfrak{M}}^* - R$ is called the **Martin boundary** of R . If \dagger Green's function g exists on R , then the function $m(p, q) = g(p, q)/g(o, q)$ for an arbitrary fixed $o \in R$ can be extended continuously to $R \times R_{\mathfrak{M}}^*$, which is called the **Martin kernel**. By the metric $d_{\mathfrak{M}}(q, r) = \sup_{p \in R_0} |m(p, q)/(1 + m(p, q)) - m(p, r)/(1 + m(p, r))|$ with a parametric disk R_0 in R , $R_{\mathfrak{M}}^*$ is \dagger metrizable. This compactification was introduced by R. S. Martin, and many applications of it to the study of HP -functions, potential theory, Markov chains, and cluster sets were obtained by M. H. Heins, Z. Kuramochi, J. L. Doob, Constantinescu and Cornea, and others.

(7) For a function f on R , $(R)\partial f/\partial n = 0$ means that there exists a relatively compact subregion R_f such that f is of class C^∞ on R outside R_f and the Dirichlet integral of f over $R - R_f$ is not greater than those of functions

on $R - R_f$ that coincide with f on the boundary of R_f . The **Kuramochi compactification** is the \mathfrak{K} -compactification $R_{\mathfrak{K}}^*$ with the family \mathfrak{K} of bounded continuous functions f on R satisfying $(R)\partial f/\partial n = 0$. The continuous function $k(p, q)$ on R such that $(R)\partial k/\partial n = 0$ vanishes in a fixed parametric disk R_0 in R and is harmonic in $R - R_0$ except for a positive \dagger logarithmic singularity at a point q can be extended continuously to $R \times R_{\mathfrak{K}}^*$, which is called the **Kuramochi kernel**. By the use of this kernel, $R_{\mathfrak{K}}^*$ is metrizable, as in the case of Martin compactification. This compactification was introduced by Kuramochi, and its important applications to the study of HD -functions, potential theory, and cluster sets were made by Kuramochi, Constantinescu and Cornea, and others.

Among compactifications (1)–(7), no boundary point in (2), (4), or (5) satisfies the \dagger first countability axiom (hence they are not metrizable), while the others are all metrizable. In (4) and (5), $\Delta_r = \Gamma$. Fig. 1 shows the relationship among the seven examples. Here $A \rightarrow B$ means that A lies over B , and $A \neq B$ means that in general neither $A \rightarrow B$ nor $B \rightarrow A$.

Fig. 1

D. Remarks

In contrast to topological compactifications (1)–(3), (4)–(7) can be regarded as potential-theoretic and have enough ideal boundary points so that one can solve the Dirichlet problem and introduce various measures there. Utilizing Green's functions, R. S. Martin [6] deduced the first important compactification and gave the integral representation of positive harmonic functions (the extension of the \dagger Poisson integral). Z. Kuramochi [3] obtained his compactification similarly by using N -Green functions introduced by himself instead of the usual Green's functions. In this compactification, the ideal boundary points can be considered to be interior points of the surfaces in a potential-theoretic sense. In case of finitely connected domains with smooth boundaries, both the Martin and Kuramochi boundaries coincide with the usual boundaries.

The Royden and Wiener compactifications were introduced as the maximal ideal spaces of respective function algebras. Their ideal boundaries contain extremely many points. However, these compactifications have elegant

properties and many applications. An analytic mapping φ of a Riemann surface R into another R' is called a Dirichlet (Fatou) mapping if φ can be extended to a continuous mapping of $R_{\mathfrak{A}}^*(R_{\mathfrak{B}}^*)$ to $R_{\mathfrak{A}}^*(R_{\mathfrak{B}}^*)$. For example, a Lindelöfian mapping (*AD*-function) is a Fatou (Dirichlet) mapping. The Dirichlet and Fatou mappings were investigated by Constantinescu, Cornea, and others.

By using the Martin boundary, Z. Kuramochi and M. Nakai proved the extension of the Evans-Selberg theorem to parabolic Riemann surfaces [3, 8]. The normal derivatives of *HD*-functions on the ideal boundaries and their applications were studied by Constantinescu, Cornea, F. Maeda, Y. Kusunoki, and others. The theory of compactification can be generalized to domains in \mathbf{R}^n , \dagger Green spaces, and harmonic spaces.

208 (X.7) Implicit Functions

A. General Remarks

Historically, a function y of x was called an implicit function of x if there was given a functional relation $f(x, y) = 0$ between x and y , but no explicit representation of y in terms of x (\rightarrow 165 Functions). Nowadays, however, the notion of implicit function is rigorously defined as follows: Suppose that a function $f(x_1, \dots, x_n, y)$ is of \dagger class C^1 in a domain G in the real $(n+1)$ -dimensional Euclidean space \mathbf{R}^{n+1} and that $f(x_1^0, \dots, x_n^0, y^0) = 0$, $f_y(x_1^0, \dots, x_n^0, y^0) \neq 0$ at a point $(x_1^0, \dots, x_n^0, y^0)$ in G . Then there is a unique function $g(x_1, \dots, x_n)$ of class C^1 in a neighborhood of the point (x_1^0, \dots, x_n^0) that satisfies $f(x_1, \dots, x_n, g(x_1, \dots, x_n)) = 0$, $y^0 = g(x_1^0, \dots, x_n^0)$ (**implicit function theorem**). The function g is called the **implicit function** determined by $f = 0$. The partial derivatives of g are given by the relation

$$\partial g / \partial x_j = -(\partial f / \partial x_j) / (\partial f / \partial y),$$

where $y = g(x_1, \dots, x_n)$. If the function f is of class C^r ($1 \leq r \leq \infty$ or $r = \omega$), then the function g is also of class C^r . In particular, when $n = 1$, letting x_1 be x , we have $dg/dx = -f_x/f_y$.

B. Jacobian Matrices and Jacobian Determinants

A mapping u from a domain G in \mathbf{R}^n into \mathbf{R}^m

$$u(x) = (u_1(x_1, \dots, x_n), \dots, u_m(x_1, \dots, x_n)),$$

$$x = (x_1, \dots, x_n),$$

is called a **mapping of class C^r** if each component u_1, \dots, u_m is of class C^r ($0 \leq r \leq \infty$ or $r = \omega$) in G . Given a mapping u of class C^1 from G into \mathbf{R}^m , we consider the following matrix, which gives rise to the differential du_x of the mapping u (\rightarrow 105 Differentiable Manifolds I):

$$\partial(u)/\partial(x) = (\partial u_j / \partial x_k)_{1 \leq j \leq m, 1 \leq k \leq n}. \quad (1)$$

This matrix is called the **Jacobian matrix** of the mapping u at x . If there is another mapping v of class C^1 from a domain containing the \dagger range U of u into \mathbf{R}^l , then we have the law of composition:

$$(\partial(v)/\partial(u))(\partial(u)/\partial(x)) = \partial(v)/\partial(x).$$

When $n = m$, the \dagger determinant of the matrix (1) is called the **Jacobian determinant** (or simply **Jacobian**), and is denoted by $D(u)/D(x)$, $D(u_1, \dots, u_n)/D(x_1, \dots, x_n)$ or

$$\frac{D(u_1, \dots, u_n)}{D(x_1, \dots, x_n)}.$$

Sometimes the notation ∂ is used instead of D ; but in the present article we distinguish the matrix from the determinant, using ∂ for the matrix and D for the determinant.

If $m=n$ and $D(u)/D(x)$ never vanishes at any point of the domain G , then u is called a **regular** (or **nonsingular**) **mapping of class C^1** . If the Jacobian $D(u)/D(x)$ is 0 at x , we say that u is **singular** at x . A mapping that is singular at every point in a set $S \subset G$ is said to be **degenerate** on S . For a regular mapping u , the sign of the Jacobian is constant in a connected domain G . If it is positive, the mapping u preserves the orientation of the coordinate system at each point in G , while if it is negative, the mapping changes the orientation. A point where u is degenerate is called a **critical point** of the mapping u , and its image under u is called a **critical value**. In general, the image of the mapping is "folded" along the set of critical points. The set of critical values of a mapping u of class C^1 (sending a domain in \mathbf{R}^n into \mathbf{R}^m) is of Lebesgue measure 0 in \mathbf{R}^m (**Sard's theorem**). If u is a regular mapping, then each point in the domain G of u has a neighborhood V such that the restriction of u on V is a \dagger topological mapping. Its inverse mapping $x(u)$ is also a regular mapping of class C^1 and satisfies the relation

$$\frac{D(u) D(x)}{D(x) D(u)} = 1$$

(**inverse mapping theorem**). If u is of class C^r ($1 \leq r \leq \infty$ or $r=\omega$), then so is its inverse mapping.

C. Functional Relations

A function $F(u_1, \dots, u_n)$ defined on a domain B in \mathbf{R}^n is called a **function with scattered zeros** if F has a zero point (i.e., there exists a point u for which $F(u)=0$) and if every open subset of B contains a point u such that $F(u) \neq 0$. Every \dagger analytic function $\neq 0$ has scattered zeros. Let $u(x)$ be a mapping from a domain G in \mathbf{R}^n into $B \subset \mathbf{R}^n$. Suppose that there exists a function $F(u)$ defined in B , of class C^r , with scattered zeros. If $F(u(x))=0$ for every x in G , then we say that the components u_1, \dots, u_n of the mapping u have a **functional relation of class C^r** or are **functionally dependent of class C^r** . In such a case, we sometimes say simply that u_1, \dots, u_n are **functionally dependent** or that they have a **functional relation**. If the components u_1, \dots, u_n of a mapping u of class C^1 are functionally dependent of class C^0 , then the Jacobian $D(u)/D(x)$ of u must vanish. Conversely, if the Jacobian $D(u)/D(x)$ of a mapping u of class C^1 is identically 0 in the domain G ,

the components u_1, \dots, u_n are functionally dependent of class C^∞ on every compact set in G (**Knopp-Schmidt theorem**) [1].

D. Implicit Functions Determined by Systems of Functions

Suppose that the \dagger rank of the Jacobian matrix of (1) is $r < m$ everywhere in G . Suppose that $u(x)$ is a mapping of class C^1 from a domain G in \mathbf{R}^n into \mathbf{R}^m , the Jacobian determinant $D(u_1, \dots, u_r)/D(x_1, \dots, x_r)$ never vanishes in G , and further $D(u_1, \dots, u_r, u_\rho)/D(x_1, \dots, x_r, x_\rho)$ is identically 0 in G for each ρ, σ with $r < \rho \leq m$, $r < \sigma \leq n$. Then the values $u_{r+1}(x), \dots, u_m(x)$ are determined by the values $u_1(x), \dots, u_r(x)$, and each u_ρ is represented as a function of class C^1 of u_1, \dots, u_r .

Let $u(x)$ be a mapping of class C^1 from a domain G in \mathbf{R}^n into \mathbf{R}^m and V the \dagger inverse image of a point u^0 . To study the properties of the set V , we assume, for simplicity, that u^0 is the origin. Suppose that the rank of the matrix $\partial(u)/\partial(x)$ is r for every point x in G and each of u_{r+1}, \dots, u_m is functionally dependent on u_1, \dots, u_r . Then each u_ρ ($r < \rho \leq m$) is a function $u_\rho(u_1, \dots, u_r)$ of u_1, \dots, u_r . The set V is empty if there is a ρ such that $u_\rho(0, \dots, 0) \neq 0$. On the other hand, if $u_\rho(0, \dots, 0)=0$ for all ρ ($r < \rho \leq m$), then V is the set of common zero points of the functions $u_1(x), \dots, u_r(x)$. Therefore, to study the set V , we can assume that $r=m \leq n$. If $m=n$, V consists of isolated points only. If $m < n$, then, changing the order of the variables x_1, \dots, x_n if necessary, we can assume that $D(u_1, \dots, u_m)/D(x_1, \dots, x_m) \neq 0$ at a point (x^0) in V . In this case, there is a unique function $\xi_\mu(x_{m+1}, \dots, x_n)$ of class C^1 ($1 \leq \mu \leq m$) in a neighborhood of (x_i^0) satisfying the following two conditions: (i) $x_\mu^0 = \xi_\mu(x_{m+1}^0, \dots, x_n^0)$; (ii) if the point (x_{m+1}, \dots, x_n) is in a neighborhood of $(x_{m+1}^0, \dots, x_n^0)$, then the point

$$(\xi_1(x_{m+1}, \dots, x_n), \dots, \xi_m(x_{m+1}, \dots, x_n),$$

$$x_{m+1}, \dots, x_n) \in V.$$

Each function ξ_μ is called an **implicit function** of x_{m+1}, \dots, x_n determined by the relations $u_1 = \dots = u_m = 0$. The \dagger total derivatives of the ξ_μ are determined from the system of linear equations

$$\sum_{k=1}^m \frac{\partial u_j}{\partial x_k} d\xi_k + \sum_{l=m+1}^n \frac{\partial u_j}{\partial x_l} dx_l = 0, \quad j=1, \dots, m.$$

The foregoing implicit function theorem is a local one. Among the **global implicit function theorems**, the following one, due to Hadamard, is useful: Let $x \mapsto y(x)$ be a mapping of class C^1 from \mathbf{R}^n into \mathbf{R}^n such that the inverse $\Phi^{-1}(x)$

of its Jacobian matrix $\Phi(x)$ is bounded in \mathbf{R}^n ; then the mapping is a \dagger diffeomorphism of class C^1 from \mathbf{R}^n onto \mathbf{R}^n .

The implicit function theorem holds also in complex spaces. Let $f_i(x_1, \dots, x_n, y_1, \dots, y_p)$, $1 \leq i \leq p$, be a system of \dagger holomorphic functions in a domain in the complex $(n+p)$ -dimensional space C^{n+p} . If (i) $f_i(x_1^0, \dots, x_n^0, y_1^0, \dots, y_p^0) = 0$, $1 \leq i \leq p$, and (ii) $D(f_1, \dots, f_p)/D(y_1, \dots, y_p)_{(x,y)=(x^0,y^0)} \neq 0$, then there exists a unique holomorphic solution $y_i = y_i(x_1, \dots, x_n)$ ($1 \leq i \leq p$) in a neighborhood of the point $x^0 = (x_1^0, \dots, x_n^0)$ that satisfies $f_i(x_1, \dots, x_n, y_1(x_1, \dots, x_n), \dots, y_p(x_1, \dots, x_n)) = 0$ ($1 \leq i \leq p$).

E. Linear Relations

Suppose that $u(x)$ is a mapping of class C^{m-1} from \mathbf{R}^1 into \mathbf{R}^m . Its components (u_1, \dots, u_m) are functions of class C^{m-1} . Then the determinant

$$\begin{vmatrix} u_1 & u_2 & \dots & u_m \\ u'_1 & u'_2 & \dots & u'_m \\ \vdots & \vdots & \ddots & \vdots \\ u_1^{(m-1)} & u_2^{(m-1)} & \dots & u_m^{(m-1)} \end{vmatrix}$$

is called the **Wronskian determinant** (or simply the **Wronskian**) of the functions u_1, \dots, u_m and is denoted by $W(u_1, u_2, \dots, u_m)$. If the functions u_1, \dots, u_m are \dagger linearly dependent, i.e., if there exist constants c_j not all zero satisfying $\sum_{j=1}^m c_j u_j(x) = 0$ identically, then the Wronskian vanishes identically. Therefore, if $W(u_1, \dots, u_m) \neq 0$, then the functions u_1, \dots, u_m are linearly independent. Conversely, if $W(u_1, \dots, u_m) = 0$ identically, and further if there is at least one nonvanishing Wronskian for $u_1, \dots, u_{i-1}, u_{i+1}, \dots, u_m$ ($1 \leq i \leq m$), then the functions u_1, \dots, u_m are linearly dependent. The necessity of the additional condition is shown by the following example: $u_1 = x^3$ and $u_2 = |x|^3$ are of class C^1 in the interval $[-1, 1]$ and linearly independent, but they satisfy $W(x^3, |x|^3) = 0$ identically. However, the additional condition is unnecessary if the functions u_1, \dots, u_m are analytic. Similar theorems are valid in a domain in a complex plane.

Furthermore, if $u(x)$ is a continuous mapping from an interval $[a, b]$ in \mathbf{R}^1 into \mathbf{R}^m , the determinant

$$G(u_1, \dots, u_m) = \begin{vmatrix} (1, 1) & \dots & (1, m) \\ (2, 1) & \dots & (2, m) \\ \vdots & \ddots & \vdots \\ (m, 1) & \dots & (m, m) \end{vmatrix},$$

$$(j, k) = \int_a^b u_j(x) u_k(x) dx$$

is called the **Gramian determinant** (or simply **Gramian**). The Gramian is the \dagger discriminant of

the quadratic form

$$\int_a^b \left(\sum_{j=1}^m \xi_j u_j(x) \right)^2 dx$$

of ξ_1, \dots, ξ_m and is equal to

$$\frac{1}{m!} \int_a^b \dots \int_a^b (\det(u_j(x_k)))^2 dx_1 \dots dx_m.$$

We always have $G(u_1, \dots, u_m) \geq 0$, and $G(u_1, \dots, u_m) = 0$ if and only if u_1, \dots, u_m are linearly dependent. The Gramian is defined if the functions u_1, \dots, u_m are \dagger square integrable in the sense of Lebesgue. In that case, the condition $G(u_1, \dots, u_m) = 0$ holds if and only if u_1, \dots, u_m are linearly dependent \dagger almost everywhere, i.e., there are constants c_1, \dots, c_m not all zero such that the relation $c_1 u_1(x) + \dots + c_m u_m(x) = 0$ holds except on a set of Lebesgue measure 0.

209 (XXI.5) Indian Mathematics

India was one of the earliest civilizations, but because it has no precise chronological record of ancient times, it is said to possess no history. Indian mathematics seems to have developed under the influence of the cult of Brahma, as did the calendar. It may also have some relation to the mathematics of the Near East and China, but this is difficult to trace. The word *ganita* (computation) appears in early religious writings; after the beginning of the Christian Era, it was classified into *pātī-gaṇita* (arithmetic), *bīja-gaṇita* (algebra), and *kṣetra-gaṇita* (geometry), thus showing some systematization. The Buddhists (notably Nagarjuna) had a kind of logic, but it had no re-

lation to mathematics. Unlike the Greeks, the Indians had no demonstrational geometry, but they had symbolic algebra and a position system of numeration.

Indian geometry was computational; Āryabhaṭa (c. 476–c. 550) computed the value of π as 3.1416; Brahmagupta (598–c. 660) had a formula to compute the area of quadrangles inscribed in a circle; and Bhāskara (1114–1185) gave a proof of the Pythagorean theorem. In trigonometry, Āryabhaṭa made a table of sines of angles between 0° and 90° for every 3.75° interval. The name “sine” is related to the Sanskrit *jya*, which referred to half of the chord of the double arc.

The Indians had a remarkable system of algebra. At the beginning they had no operational symbols and described in words the rules for solving equations. Brahmagupta worked on the \dagger Pell equation $ax^2 + 1 = y^2$. Bhāskara knew that a quadratic equation can have two roots that can be positive and negative, but did not assign any meaning to the negative root in such cases. Bhāskara also introduced algebraic symbols.

The symbol 0 was used in India from about 200 B.C. to denote the void place in the position system of numeration; 0 as a number is found in a book by Bakhshālī published in the 3rd century A.D. The number 0 is defined as $a - a = 0$ in our notation, and the rules $a \pm 0 = a$, $0 \times a = 0$, $\sqrt{0} = 0$, $0 \div a = 0$ are mentioned. Brahmagupta prohibited division by 0 in arithmetic, but in algebra he called the “quantity” $a \div 0$ *taccheda*. Bhāskara called it *kahara* and made it play a role similar to that of our infinity.

Some historians assert that the Indians had the ideas of infinity and infinitesimal. Some hold that the Indian position system of numeration arose from the circumstance that the names of numbers differed according to their positions. The Indian numeration system was exported to Europe through Arabia, and had great influence on the development of mathematics.

210 (II.25) Inductive Limits and Projective Limits

A. General Remarks

Inductive and projective limits can be defined over any \dagger preordered set I and in any \dagger category. We first explain the definition of these limits in the special case where I is a \dagger directed set and the category is that of sets, of groups, or of topological spaces. The simplest case is when I is the ordered set \mathbb{N} of the natural numbers.

B. The Limit of Sets

Let I be a directed set. Suppose that we are given a set X_i for each $i \in I$ and a mapping $\varphi_{ji}: X_i \rightarrow X_j$ for each pair (i, j) of elements of I with $i \leq j$, such that $\varphi_{ii} = 1_{X_i}$ (the identity mapping on X_i) and $\varphi_{ki} = \varphi_{kj} \circ \varphi_{ji}$ ($i \leq j \leq k$). Then we denote the system by (X_i, φ_{ji}) and call it an **inductive system** (or **direct system**) of sets over I . Let S be the \dagger direct sum $\coprod_i X_i$ of the sets X_i ($i \in I$), and define an equivalence relation in S as follows: $x \in X_i$ and $y \in X_j$ are equivalent if and only if there exists a $k \in I$ such that $i \leq k$, $j \leq k$, $\varphi_{ki}(x) = \varphi_{kj}(y)$. Let D be the \dagger quotient set of S by this equivalence relation, and let $f_i: X_i \rightarrow D$ ($i \in I$) be the canonical mappings. Then we have I(1) $f_j \circ \varphi_{ji} = f_i$ ($i \leq j$); I(2) for any set X , and for any system of mappings $g_i: X_i \rightarrow X$ ($i \in I$) satisfying $g_j \circ \varphi_{ji} = g_i$ ($i \leq j$), there exists a unique mapping $f: D \rightarrow X$ such that $f \circ f_i = g_i$ ($i \in I$). We call (D, f_i) the **inductive limit** (or **direct limit**) of the inductive system (X_i, φ_{ji}) over I , and denote it by $\lim X_i$ or $\text{ind } \lim X_i$ (more precisely, by $\varinjlim_{i \in I} X_i$ or $\text{ind } \lim_{i \in I} X_i$).

Suppose, dually, that we are given a set X_i for each $i \in I$ and a mapping $\psi_{ij}: X_j \rightarrow X_i$ for each $i \leq j$, such that $\psi_{ii} = 1_{X_i}$ and $\psi_{ik} = \psi_{ij} \circ \psi_{jk}$ ($i \leq j \leq k$). Then we denote the system by (X_i, ψ_{ij}) and call it a **projective system** (or **inverse system**) of sets over I . Let P be the subset of the Cartesian product $\prod X_i$ defined by $P = \{(x_i) \mid \psi_{ij}(x_j) = x_i \text{ (} i \leq j \text{)}\}$, and let $p_i: P \rightarrow X_i$ be the canonical mappings. Then we have P(1) $\psi_{ij} \circ p_j = p_i$ ($i \leq j$); P(2) for any set X , and for any system of mappings $q_i: X \rightarrow X_i$ satisfying $\psi_{ij} \circ q_j = q_i$ ($i \leq j$), there exists a unique mapping $p: X \rightarrow P$ such that $p_i \circ p = q_i$ ($i \in I$). We call (P, p_i) the **projective limit** (or **inverse limit**) of the projective system (X_i, ψ_{ij}) over I and denote it by $\lim X_i$ or $\text{proj } \lim X_i$.

Note that we may replace I by any cofinal subset of I without changing the limits.

C. The Limit of Groups and of Topological Spaces

If, in the notation of Section B, X_i is a group and $\varphi_{ji}(\psi_{ij})$ is a homomorphism, then we say that (X_i, φ_{ji}) ((X_i, ψ_{ij})) is an **inductive (projective) system of groups**. The inductive limit (as a set) $D = \varinjlim X_i$ has the structure of a group for which the canonical mappings f_i are homomorphisms. With this group structure, D is called the **inductive limit (group)** of the inductive system of groups. It satisfies properties I(1) and I(2) with group X and homomorphisms g_i and f . Similarly, the projective limit (as a set) $P = \varprojlim X_i$ has a unique group structure such that each $p_i: P \rightarrow X_i$ is a homomorphism, namely, that of a subgroup of the direct product group $\prod X_i$. The group P is called the **projective limit (group)** of the projective system of groups. When each X_i is a module over a fixed ring A , we get entirely similar results by considering A -homomorphisms instead of group homomorphisms.

Next, let X_i be a topological space and φ_{ji} and ψ_{ij} be continuous mappings. Then (X_i, φ_{ji}) ((X_i, ψ_{ij})) is called an **inductive (projective) system of topological spaces**. If we introduce in $D = \varinjlim X_i$ the topology of a quotient space of the topological direct sum of the spaces X_i ($i \in I$), then the f_i are continuous, and I(1) and I(2) hold with sets and mappings replaced by topological spaces and continuous mappings. Similarly, if we view $P = \varprojlim X_i$ as a subspace of the \dagger product space $\prod X_i$, then the p_i are continuous and P(1) and P(2) hold with the same modification as before. The spaces D and P are called the **inductive limit (space)** and the **projective limit (space)** of the system of topological spaces, respectively. The projective limit of Hausdorff (compact) spaces is also Hausdorff (compact).

Furthermore, if the X_i ($i \in I$) form a topological group and φ_{ji}, ψ_{ij} are continuous homomorphisms, then $\varinjlim X_i$ and $\varprojlim X_i$ are topological groups, and properties I(1), I(2), P(1), and P(2) are satisfied for topological groups and continuous homomorphisms (\rightarrow 423 Topological Groups). In particular, projective limits of finite groups are \dagger totally disconnected compact groups and are called **profinite groups**; they occur, e.g., as the ring of $\dagger p$ -adic integers and as the \dagger Galois group of an infinite \dagger Galois extension. Conversely, the \dagger germs of continuous functions at a point x in a topological space X , and other kinds of germs (\rightarrow 383 Sheaves), are important examples of inductive limits of groups.

D. Limits in a Category

Let I be a preordered set and \mathcal{C} a category. If we are given an object X_i of a category \mathcal{C} for each $i \in I$ and a \dagger morphism $\varphi_{ji}: X_i \rightarrow X_j$ of \mathcal{C} for each pair (i, j) of elements of I with $i \leq j$, and if the conditions $\varphi_{ii} = 1_{X_i}$, $\varphi_{ki} = \varphi_{kj} \circ \varphi_{ji}$ ($i \leq j \leq k$) are satisfied, then we call the system (X_i, φ_{ji}) an **inductive system** over I in the category \mathcal{C} . A **projective system** in \mathcal{C} is defined dually: It is an inductive system in the \dagger dual category \mathcal{C}° . If we view I as a category (\rightarrow 52 Categories and Functors B), then an inductive (projective) system in \mathcal{C} over the index set I is a \dagger covariant (\dagger contravariant) functor from I to \mathcal{C} . Now if an object $D \in \mathcal{C}$ and morphisms $f_i: X_i \rightarrow D$ ($i \in I$) satisfy conditions I(1) and I(2) with the modification that X is an object and g_i, f are morphisms in \mathcal{C} , then the system (D, f_i) is called the **inductive limit** of (X_i, φ_{ji}) and is denoted by $\varinjlim X_i$. Similarly, if an object $P \in \mathcal{C}$ and morphisms $p_i: P \rightarrow X_i$ ($i \in I$) satisfy P(1) and P(2) with a similar modification, then (P, p_i) is called the **projective limit** of (X_i, ψ_{ij}) and is written $\varprojlim X_i$. By I(2) and P(2), these limits are unique if they exist.

In the categories of sets, of groups, of modules, and of topological spaces, inductive and projective limits always exist. Note that if the ordering of I is such that $i \leq j$ implies $i = j$, i.e., if there is no ordering between two distinct elements of I , then the inductive (projective) limit is the \dagger direct sum (\dagger direct product) (\rightarrow 52 Categories and Functors E).

Let (X_i, φ_{ji}) , (X'_i, φ'_{ji}) be two inductive systems over the same index set I , and let $\varphi_i: X_i \rightarrow X'_i$ ($i \in I$) be morphisms satisfying $\varphi'_{ji} \circ \varphi_i = \varphi_i \circ \varphi_{ji}$ ($i \leq j$). Then the system (φ_i) is called a **morphism** between the inductive systems. Such a morphism is a \dagger natural transformation between the inductive systems viewed as functors $I \rightarrow \mathcal{C}$. If $\varinjlim X_i$ and $\varinjlim X'_i$ exist, then (φ_i) induces a morphism $\varinjlim \varphi_i: \varinjlim X_i \rightarrow \varinjlim X'_i$ in a natural way, and similarly for projective limits.

For the more abstract notion of limit of a functor \rightarrow [5]. For the theory of procategories \rightarrow [4].

211 (X.3) Inequalities

A. General Remarks

In this article we consider various properties of inequalities between real numbers. An inequality that holds for every real number (e.g., $x^2 \geq 0$) is called an **absolute inequality**; otherwise it is called a **conditional inequality**. When we are given a conditional inequality (e.g., $x(x-1) < 0$), the set of all real numbers that satisfy it is called the **solution** of the inequality. The process of obtaining a solution is called **solving** the conditional inequality.

B. Solution of a Conditional Inequality

Suppose that a conditional inequality is given by $f(x) > 0$ (or $f(x) \geq 0$), where f is a continuous function defined for every real number. If the equation $f(x) = 0$ has no solution, then we have either $f(x) > 0$ or $f(x) < 0$ for all x . On the other hand, if α and β ($\alpha < \beta$) are adjacent roots of the equation $f(x) = 0$, the sign of $f(x)$ is unchanged in the open interval (α, β) . Therefore the solution of the given inequality depends essentially on the solution of the equation $f(x) = 0$. If inequalities involve two variables x, y and are given by $f(x, y) > 0$, $g(x, y) > 0$ for continuous functions f and g , the solution is, in general, a domain in the xy -plane bounded by the curves $f(x, y) = 0$ and $g(x, y) = 0$. Similar results hold for the case of inequalities involving more than two variables.

C. Famous Absolute Inequalities

(1) Inequalities concerning **means** (or **averages**): Suppose that we are given an n -tuple $a = (a_1, \dots, a_n)$, $a_r \geq 0$. We set

$$M_r = M_r(a) = \left(\frac{1}{n} \sum_{v=1}^n a_v^r \right)^{1/r}.$$

If at least one a_r is 0 and $r < 0$, we put $M_r = 0$. In particular, we put

$$A = M_1,$$

$$G = \lim_{r \rightarrow \infty} M_r = \left(\prod_{v=1}^n a_v \right)^{1/n},$$

$$H = M_{-1};$$

these are called the **arithmetic mean**, **geometric mean**, and **harmonic mean** of a_v ($v = 1, \dots, n$), respectively. Except when either all a_v are identical or some a_v is 0 and $r \leq 0$, the function M_r increases [†]strictly monotonically as r increases, and $M_r \rightarrow \min a_v$ ($r \rightarrow -\infty$), $M_r \rightarrow \max a_v$ ($r \rightarrow +\infty$). Therefore we always have $\min a_v \leq M_r \leq \max a_v$. In particular, we have $H < G < A$ if the a_v are all positive and not all equal.

Let $p(x) (> 0)$, $f(x) (\geq 0)$ be [†]integrable functions on a [†]measurable set E . We put

$$M_r(f) = \left(\int_E p f^r dx / \int_E p dx \right)^{1/r}, \quad r \neq 0.$$

Furthermore, if $M_r(f)$ is strictly positive for some $r > 0$, we put

$$\begin{aligned} M_0(f) &= \lim_{r \rightarrow +0} M_r(f) \\ &= \exp \left(\int_E p \log f dx / \int_E p dx \right). \end{aligned}$$

We call $M_r(f)$ the **mean of degree r** of the function $f(x)$ with respect to the **weight function** $p(x)$. It has properties similar to those of $M_r(a)$. In particular, when the weight function $p = 1$, the means $M_1(f)$, $M_0(f)$, $M_{-1}(f)$ are called the **arithmetic mean**, **geometric mean**, and **harmonic mean** of f , respectively.

(2) The Hölder inequality: Suppose that $p \neq 0, 1$ and $(p-1)(q-1) = 1$; that is, $1/p + 1/q = 1$, and $a_v > 0$, $b_v > 0$. Then, in general, we have the **Hölder inequality**:

$$\sum_v a_v b_v \leq \left(\sum_v a_v^p \right)^{1/p} \left(\sum_v b_v^q \right)^{1/q}, \quad p \leq 1,$$

where the inequality signs in the first inequality are taken in accordance with $p < 1$ or $p > 1$. The summation may be infinite if the sums are convergent. The inequality sign is replaced by the equality sign if and only if there exist constant factors λ and μ such that $\lambda a_v^p = \mu b_v^q$ for all v . The Hölder inequality for $p = q = 2$ is called the **Cauchy inequality** (or **Cauchy-Schwarz inequality**).

For two measurable positive functions $f(x)$, $g(x)$, we have the **Hölder integral inequality**:

$$\int_E f g dx \leq \left(\int_E f^p dx \right)^{1/p} \left(\int_E g^q dx \right)^{1/q}, \quad p \leq 1,$$

except when there exist two constant factors λ and μ ($(\lambda, \mu) \neq (0, 0)$) such that $\lambda f^p = \mu g^q$ holds [†]almost everywhere. The above inequality is replaced by equality if and only if we are in this exceptional case. The case where $p = q = 2$ is called the **Schwarz inequality** (or **Bunyakovskii inequality**).

(3) The Minkowski inequality: Suppose that $p \neq 0, 1$ and $a_v > 0$, $b_v > 0$. Then we have the

Minkowski inequality:

$$\left(\sum_v (a_v + b_v)^p\right)^{1/p} \geq \left(\sum_v a_v^p\right)^{1/p} + \left(\sum_v b_v^p\right)^{1/p},$$

$$p \leq 1,$$

except when $\{a_v\}$ and $\{b_v\}$ are proportional. The inequality is replaced by equality if and only if we are in the exceptional case.

The corresponding integral inequality for positive functions $f(x)$, $g(x)$ is

$$\left(\int_E (f+g)^p dx\right)^{1/p} \geq \left(\int_E f^p dx\right)^{1/p} + \left(\int_E g^p dx\right)^{1/p}, \quad p \leq 1,$$

except when $f(x)/g(x)$ is constant almost everywhere. The inequality is replaced by equality if and only if we are in the exceptional case.

D. Related Topics

Absolute inequalities are important in analysis, especially in connection with techniques to prove convergence or for error estimates. However, there seldom are general principles for deriving such inequalities, except for a few elementary theorems.

For other famous inequalities → Appendix A, Table 8. For related topics → 88 Convex Analysis; for convex functions and their applications → 255 Linear Programming; for linear inequalities → 212 Inequalities in Physics.

**212 (XX.36)
Inequalities in Physics****A. Correlation Inequalities**

Let μ be a probability measure on a space X (with σ -field \mathcal{B}) and f_j be measurable functions on X , and write

$$\langle f_1 \dots f_n \rangle = \int_X f_1(x) \dots f_n(x) d\mu(x).$$

A number of inequalities among such expectations under a variety of conditions on the measure μ and functions f_j are known as correlation inequalities, after their original occurrence for correlation functions in the statistical mechanics of lattice gases.

The earliest results were obtained by Griffiths (*J. Math. Phys.*, 8 (1967)), for the case where X is the product $\prod_{i=1}^N I_i$ of two point sets $I_i = \{1, -1\}$, the f are k th coordinate functions $\sigma_k = \sigma_k(x)$ ($= \pm 1$) of $x \in X$, $d\mu(x)$ is the counting measure multiplied by a Gibbs factor $Z^{-1} e^{-\beta H(x)}$ with a ferromagnetic Hamiltonian

$$H(x) = - \sum_{i < j} J_{ij} \sigma_i(x) \sigma_j(x), \quad J_{ij} = J_{ji} \geq 0,$$

$\beta \geq 0$, and the normalization factor $Z = \sum_x e^{-\beta H(x)}$. His conclusions are

$$\langle \sigma_k \sigma_l \rangle \geq 0 \quad (\text{Griffiths's first inequality}),$$

$$\langle \sigma_k \sigma_l \sigma_m \sigma_n \rangle \geq \langle \sigma_k \sigma_l \rangle \langle \sigma_m \sigma_n \rangle$$

(Griffiths's second inequality).

These were extended by Kelly and Sherman (*J. Math. Phys.*, 9 (1968)) as

$$\langle \sigma_A \rangle \geq 0 \quad (\text{GKS first inequality}),$$

$$\langle \sigma_A \sigma_B \rangle \geq \langle \sigma_A \rangle \langle \sigma_B \rangle$$

(GKS second inequality),

where A and B are subsets of $\{1, \dots, N\}$, $\sigma_A = \prod_{i \in A} \sigma_i$, and $H = - \sum_{A \subset N} J_A \sigma_A$ with $J_A \geq 0$. A further generalization (for example, $I_i = \mathbf{R}$) can be found in [1, 2].

Under the same situation with

$$H = - \sum_{i < j} J_{ij} \sigma_i \sigma_j - \sum_{i=1}^N h_i \sigma_i, \quad J_{ij} \geq 0, \quad h_i \geq 0,$$

the following GHS inequality by Griffiths, Hurst, and Sherman (*J. Math. Phys.*, 11 (1970)) holds:

$$\begin{aligned} \langle \sigma_i \sigma_j \sigma_k \rangle - \langle \sigma_i \rangle \langle \sigma_j \sigma_k \rangle - \langle \sigma_j \rangle \langle \sigma_i \sigma_k \rangle \\ - \langle \sigma_k \rangle \langle \sigma_i \sigma_j \rangle + 2 \langle \sigma_i \rangle \langle \sigma_j \rangle \langle \sigma_k \rangle \leq 0. \end{aligned}$$

If $h_i = 0$ for all i , then

$$\begin{aligned} \langle \sigma_i \sigma_j \sigma_k \sigma_l \rangle - \langle \sigma_i \sigma_l \rangle \langle \sigma_j \sigma_k \rangle - \langle \sigma_j \sigma_l \rangle \langle \sigma_i \sigma_k \rangle \\ - \langle \sigma_k \sigma_l \rangle \langle \sigma_i \sigma_j \rangle + 2 \langle \sigma_i \sigma_l \rangle \langle \sigma_j \sigma_l \rangle \langle \sigma_k \sigma_l \rangle \leq 0. \end{aligned}$$

Further generalizations can be found in [2, 3], and the references quoted therein.

Let X be a finite distributive lattice, μ be a positive measure satisfying the condition $\mu(x \wedge y)\mu(x \vee y) \geq \mu(x)\mu(y)$, and f and g be both increasing or both decreasing functions on X . Then the following FKG inequality by Fortuin, Kasteleyn, and Ginibre (*Comm. Math. Phys.*, 22 (1971)) holds:

$$\langle fg \rangle \geq \langle f \rangle \langle g \rangle.$$

B. Inequalities Involving Traces of Matrices

Let $\text{tr } A$ denote the trace of a matrix A . Some of the earlier results applied to statistical mechanics are as follows, where $\rho \geq 0$, $\sigma \geq 0$, $A^* = A$, $B^* = B$:

$$\text{tr}(\rho \log \rho - \rho \log \sigma - \rho + \sigma) \geq 0$$

(Klein inequality),

$$\text{tr}(e^{A+B})/\text{tr } e^A \geq \exp(\text{tr } e^A B / \text{tr } e^A)$$

(Peierls-Bogolyubov inequality),

$$\text{tr}(e^A e^B) \geq \text{tr}(e^{A+B})$$

(Golden-Thompson inequality).

The following inequality is related to the last inequality and was proved for a general $m \geq 0$ by Lieb and Thirring (*Studies in Mathematical Physics*, Lieb, Simon, and Wightman (eds.), Princeton Univ. Press, 1976):

$$\text{tr}(\rho \sigma)^m \leq \text{tr}(\rho^m \sigma^m), \quad \rho \geq 0, \quad \sigma \geq 0.$$

For the Hilbert-Schmidt norm $\|A\|_{\text{H.S.}} \equiv (\text{tr } A^* A)^{1/2}$ and the trace-class norm $\|A\|_{\text{tr}} \equiv \text{tr}|A|$, where $|A| = (A^* A)^{1/2}$, the Powers-Størmer inequality (*Comm. Math. Phys.*, 16 (1970)) holds:

$$\|\rho^2 - \sigma^2\|_{\text{tr}} \geq (\|\rho - \sigma\|_{\text{H.S.}})^2, \quad \rho \geq 0, \quad \sigma \geq 0.$$

Araki and Yamagami (*Comm. Math. Phys.*, 81 (1981)) give

$$\| |C| - |D| \|_{\text{H.S.}} \leq \sqrt{2} \|C - D\|_{\text{H.S.}}$$

If $C^* = C$ and $D^* = D$, then $\sqrt{2}$ can be removed.

The entropy $S(\rho) = -\text{tr } \rho \log \rho$ is a concave function of $\rho \geq 0$ satisfying the triangular inequality (Araki and Lieb, *Comm. Math. Phys.*, 18 (1970)):

$$S(\rho_1) + S(\rho_2) \geq S(\rho_{12}) \geq |S(\rho_1) - S(\rho_2)|$$

and strong subadditivity (Lieb and Ruskai, *J. Math. Phys.*, 14 (1973)):

$$S(\rho_{123}) - S(\rho_{12}) - S(\rho_{13}) + S(\rho_1) \leq 0,$$

where ρ_{123} is a matrix on the tensor product space $H_1 \otimes H_2 \otimes H_3$, $\rho_{jk} = \text{tr}_i \rho_{123}$, $\rho_i = \text{tr}_j \text{tr}_k \rho_{123}$ ($\{i, j, k\} = \{1, 2, 3\}$) and tr_j is a (partial) trace taken only on the space H_j . The

last inequality is based on the concavity of the function $f(\rho) = \text{tr} \exp(A + \log \rho)$ in $\rho \geq 0$ ($A^* = A$) proved by Lieb [4] (also see Epstein, *Comm. Math. Phys.*, 31 (1973)), who also proved the joint concavity of $\text{tr}(C^* \rho^s C \sigma^r)$ ($r \geq 0, s \geq 0, r + s \leq 1$) in $\rho \geq 0$ and $\sigma \geq 0$. This concavity for the case $r = s = 1/2$ was previously proved by Wigner and Yanase (*Proc. Nat. Acad. Sci. US*, 49 (1963)), and the general case has been conjectured by Wigner, Yanase, and Dyson. It leads to the joint concavity of the relative entropy $S(\rho, \sigma) = \text{tr } \rho(\log \rho - \log \sigma)$ (defined to be $+\infty$ if $\sigma \psi = 0$ and $\rho \psi \neq 0$ for some vector ψ) in $\rho \geq 0$ and $\sigma \geq 0$ as well as its monotonicity $S(\alpha(\rho), \alpha(\sigma)) \leq S(\rho, \sigma)$ for any trace-preserving expectation mapping α . (For entropy, see also [5].)

The above results have generalizations in the context of von Neumann algebras (Araki, *Publ. Res. Inst. Math. Sci.*, 11 (1975); 13 (1977); Uhlmann, *Comm. Math. Phys.*, 54 (1977); [6]).

C. Operator Monotone and Operator Convex Functions

A real-valued function $f(x)$ defined on an interval I (finite or infinite; open, half-open, or closed) is called matrix monotone increasing (decreasing) of order m if $f(A) \geq f(B)$ whenever $m \times m$ Hermitian matrices A and B with their eigenvalues contained in I satisfy $A \geq B$ ($A \leq B$) and is called operator monotone if it is matrix monotone of order n for all positive integers n . $f(x)$ is called matrix convex of order m if $f[(1-t)A + tB] \leq (1-t)f(A) + tf(B)$ for $0 \leq t \leq 1$ and all $m \times m$ Hermitian matrices A and B with their eigenvalues in I and is called operator convex if it is matrix convex of order n for any positive integer n . The functions x^α ($0 \leq \alpha \leq 1$), $\log x$, and $-(x+a)^{-1}$ ($a \geq 0$) are all operator monotone increasing in the half-line interval $x > 0$. The functions $(x+a)^{-1}$ and $x \log x$ are operator convex in the same interval.

A function $f(x)$ is operator monotone increasing in an open interval (a, b) if and only if it is analytic in (a, b) and has an analytic continuation to the whole upper half-plane where the function has a nonnegative imaginary part [7]. Another necessary and sufficient condition is

$$\sum_{i,k=0}^N f^{(i+k+1)}(x) \zeta_i \zeta_k / (i+k+1)! \geq 0$$

for all $x \in (a, b)$, for all real ζ , and for all positive integers N . An operator monotone function $f(x)$ on an open interval $(-R, R)$ has the integral representation

$$f(x) = f(0) + f'(0) \int x/(1-tx) d\mu(t),$$

where μ is a probability measure with its support contained in $[-R^{-1}, R^{-1}]$ and, if f is not a constant, is uniquely determined by f . The set of all extremal points of the set of all operator monotone increasing functions on $(-1, 1)$ satisfying $f(0)=0$ and $f'(0)=1$ is exactly the set of functions $x/(1-tx)$, $|t| \leq 1$, which appear as integrands in the above formula. An operator monotone function on \mathbf{R} must be linear.

An operator convex function in an open interval $(-R, R)$ has the integral representation

$$f(x) = f(0) + f'(0)x + (f''(0)/2) \int x^2/(1-tx) d\mu(t),$$

where μ is a probability measure with its support contained in $[-R^{-1}, R^{-1}]$ and, if f is not linear, is uniquely determined by f . An operator convex function in \mathbf{R} must be at most a quadratic polynomial satisfying $f''(0) \geq 0$.

For a continuous real function on an interval $[0, \alpha)$ ($0 \leq \alpha < \infty$), the following four conditions are mutually equivalent: (i) f is operator convex and $f(0) \leq 0$, (ii) $f(a^*Aa) \leq a^*f(A)a$ for any self-adjoint operator A with its spectrum in $[0, \alpha)$ and any operator a with its norm not exceeding 1, (iii) the preceding condition with a limited to projections, (iv) $x^{-1}f(x)$ is operator monotone increasing in an open interval $(0, \alpha)$. (See [8–11] and Hansen and Pedersen, Jensen's inequality for operators and Löwner's theorem, *Math. Ann.*, 258 (1982), 229–241.

213 (XIX.12) Information Theory

A. General Remarks

The mathematical theory of information transmission in communication systems, first developed by C. E. Shannon [1] and now called **information theory**, is one of the most important fields of mathematical science. It consists of two main themes, **channel coding theory** and **source coding theory**. The purpose of channel coding theory is to ascertain the existence of schemes for transmitting information or data reliably over a **noisy channel** at a fixed transmission rate. The purpose of source coding theory is to show the existence of schemes for compressing data emitted from an **information source** and reproducing them within tolerable limits of distortion. Both theories are based profoundly on the theory of probability, statistics, and the theory of stochastic processes.

B. Entropy

In information theory it is customary to call a finite set $A = \{\alpha_1, \dots, \alpha_n\}$ an **alphabet** and to call its elements the **letters** of the alphabet. The simplest model of information sources consisting of an alphabet A and a \dagger probability distribution p over A is denoted by $X = [A, p]$, which can be regarded as a \dagger finite probability space, where the probability of outcome of a letter $\alpha_i \in A$ from the source is denoted by $p_i = p(\alpha_i)$. A real-valued function defined by $I(\alpha_i) = -\log p(\alpha_i)$ is called the **self-information** of the event $\alpha_i \in A$. The \dagger mean value of the self-information, i.e.,

$$H(X) = \sum_{i=1}^n -p(\alpha_i) \log p(\alpha_i),$$

is called the **entropy** of the source. This can be interpreted as a measure of the average a priori uncertainty as to which letter will emanate from the source, or a measure of the average amount of information one obtains upon receiving a single letter from the source. The unit of information or entropy for base e logarithms is called a **nat**, while that for base 2 logarithms is called a **bit**.

Let $A = \{\alpha_1, \dots, \alpha_n\}$ and $B = \{\beta_1, \dots, \beta_m\}$ be two alphabets. Let $r(\alpha_i, \beta_j)$ be a †joint probability distribution defined on the product AB , and denote the †probability space by $XY = [AB, r]$. Then the joint distribution gives rise to †marginal distributions $p(\alpha_i) = \sum_{j=1}^m r(\alpha_i, \beta_j)$ and $q(\beta_j) = \sum_{i=1}^n r(\alpha_i, \beta_j)$ and to †conditional distributions $p(\alpha_i | \beta_j) = r(\alpha_i, \beta_j)/q(\beta_j)$ and $q(\beta_j | \alpha_i) = r(\alpha_i, \beta_j)/p(\alpha_i)$. Probability spaces $X = [A, p]$ and $Y = [B, q]$ are subspaces of the probability space $XY = [AB, r]$. The entropy of $XY = [AB, r]$ is defined by

$$H(XY) = \sum_{i=1}^n \sum_{j=1}^m -r(\alpha_i, \beta_j) \log r(\alpha_i, \beta_j)$$

as well. A real-valued function $I(\alpha_i | \beta_j) = -\log p(\alpha_i | \beta_j)$ is called the **conditional self-information**. The average of $I(\alpha_i | \beta_j)$ over α_i defined by

$$H(X | \beta_j) = \sum_{i=1}^n p(\alpha_i) I(\alpha_i | \beta_j)$$

is called the **conditional entropy** of X for given $\beta_j \in B$. The average of $H(X | \beta_j)$ over β_j defined by

$$H(X | Y) = \sum_{j=1}^m q(\beta_j) H(X | \beta_j)$$

is called the conditional entropy of X for given Y . The conditional entropy of Y for given X , denoted by $H(Y | X)$, is defined similarly. Then it can be shown that

$$H(XY) = H(Y) + H(X | Y) = H(X) + H(Y | X),$$

$$H(XY) \leq H(X) + H(Y),$$

$$H(X | Y) \leq H(X),$$

$$H(Y | X) \leq H(Y),$$

where equalities in the last three expressions hold if and only if $r(\alpha_i, \beta_j) = p(\alpha_i)q(\beta_j)$ for all $\alpha_i \in A$ and $\beta_j \in B$.

C. Information Sources

Given a finite alphabet A , we consider the finite product set $A^N = A \times \dots \times A$ and the doubly infinite product $A^Z = \prod_{k=-\infty}^{\infty} A_k$, where $A_k = A$, $k = 0, \pm 1, \pm 2, \dots$. Let \mathcal{F}_A be the σ -algebra generated by all †cylinder sets in A^Z . Given a †probability measure P over \mathcal{F}_A , an information source is defined as a probability space $[A^Z, P]$ or as a †random process $\mathbf{X} = \dots X_{-1} X_0 X_1 X_2 \dots$. When P is invariant under the †shift transformation T on A^Z , i.e., $P(E) = P(TE)$ for any $E \in \mathcal{F}_A$, then $[A^Z, P]$ is said to be a **stationary source**. In particular, if $P(E) = 0$ or 1 whenever $TE = E \in \mathcal{F}_A$, then the information source is said to be **ergodic**. If \mathbf{X} is an †independently and identically distributed

random process, the source $\mathbf{X} = [A^Z, P]$ is said to be **memoryless**.

For a given \mathbf{X} , denote the subsequence $X_1 \dots X_N$ of \mathbf{X} by X^N . Then a probability measure P on A^N and a finite probability space $X^N = [A^N, P^N]$ are naturally induced. The entropy of the stationary information source $\mathbf{X} = [A^Z, P]$ is defined as $H(\mathbf{X}) = \lim_{N \rightarrow \infty} H(X^N)/N$ or as $H(\mathbf{X}) = \lim_{N \rightarrow \infty} H(X_N | X^{N-1})$, because both limits exist and are identical. If \mathbf{X} is memoryless, the entropy of \mathbf{X} is equivalent to that of $X_1 = [A^1, P^1]$, i.e., $H(\mathbf{X}) = \sum_{i=1}^n -p_i \log p_i$, where $p_i = p^1(X_1 = \alpha_i)$ and $H(X^N) = NH(X^1) = NH(\mathbf{X})$.

D. Source Coding Theorem

Let $x^N = x_1 \dots x_N$ be a sequence of N consecutive letters from the source $[A^Z, P]$. Suppose that we wish to encode such sequences into fixed-length code words $u^L = u_1 \dots u_L$ consisting of L letters from a code alphabet U of size v . The number $R = (\log v^L)/N$ is called the **coding rate** per source letter. A mapping $\varphi: A^N \rightarrow U^L$ is called an encoder and $\varphi: U^L \rightarrow A^N$ a decoder. The set U^L with specified encoder-decoder pair $[\varphi, \psi]$ is called a **code** with rate $R = (L \log v)/N$. The **error probability** of the code is defined by

$$P_e[\varphi, \psi] = P[\psi\{\varphi(X^N) \neq X^N\}].$$

The fixed-length **source coding theorem** [1, 2] states: Let $\mathbf{X} = [A^Z, P]$ be a stationary ergodic source. Then for any $\delta > 0$, if $R \geq H(\mathbf{X}) + \delta$, there exists a code $[\varphi, \psi]$ with rate R such that the error probability $P_e[\varphi, \psi]$ can be made arbitrarily small by making N sufficiently large. Conversely, if $R \leq H(\mathbf{X}) - \delta$ then for any code with rate R , $P_e[\varphi, \psi]$ must become arbitrarily close to 1 as $N \rightarrow \infty$.

This theorem is trivial if $R \geq \log n$. For memoryless sources, the theorem follows immediately from the †weak law of large numbers, which implies that for arbitrary $\varepsilon > 0$ and $\delta > 0$ there exists an integer $N_0(\varepsilon, \delta)$ such that for all $N > N_0(\varepsilon, \delta)$

$$P\left[\left|\frac{-\log P^N(X^N)}{N} - H(\mathbf{X})\right| > \delta\right] < \varepsilon.$$

The validity of this property for stationary ergodic sources was proved by B. McMillan [2]. In case of memoryless sources, the exact asymptotic form of the error probability for an optimal code with rate R was given by F. Jelinek [3], I. Csiszár and G. Longo [4], Blahut [5], and Longo and A. Sgarro [6] as

$$\lim_{N \rightarrow \infty} -\frac{1}{N} \log P_e[\varphi, \psi] = \min_{q: H(q) \geq R} D(q \| p),$$

where p is the source distribution, q denotes a

probability distribution on A , and

$$D(q \| p) = \sum_{i=1}^n q_i \log \frac{q_i}{p_i},$$

which is called **Kullback's discrimination information** [7] or the **divergence**.

Source sequences x^N can be encoded into variable-length code words consisting of letters from alphabet U of size v . A set of n^N code words is called a **prefix condition code** if there is no code word which is equivalent to the prefix of any other code word. Denote the length of the code word corresponding to a source sequence x^N by $L(x^N)$ and the average length of the code words per source letter by

$$\frac{1}{N} \bar{L} = \sum_{x^N} \frac{1}{N} P^N(x^N) L(x^N).$$

The variable length source coding theorem states: Given a memoryless source \mathbf{X} with entropy $H(\mathbf{X})$, there is a prefix condition code such that the average length of the code words per source letter satisfies

$$H(\mathbf{X}) \leq \bar{L} \log v \leq H(\mathbf{X}) + \frac{1}{N} \log v.$$

This theorem is valid for stationary ergodic sources if $(\log v)/N$ in the last term is replaced by $\varepsilon(N)$, where $\varepsilon(N) \rightarrow 0$ as $N \rightarrow \infty$.

These two theorems are referred to as **noiseless source coding theorems**.

E. Source Coding Theorem with Fidelity Criterion

The noiseless source coding theorem implies that the average number of code letters per source letter can be reduced to the source entropy $H(\mathbf{X})$ under the requirement that the source sequence be exactly reproduced from the encoded sequence. If an approximate reproduction of the source sequence to within a given fidelity criterion is required, the coding rate per source letter must be reduced further to a certain value below the source entropy.

Suppose that a **distortion measure** $d(\alpha_i, \alpha_j)$ is defined for $\alpha_i, \alpha_j \in A$, where it is assumed that $d(\alpha_i, \alpha_j) \geq 0$ and $d(\alpha_i, \alpha_i) = 0$. For blocks $x^N = x_1 \dots x_N$ and $y^N = y_1 \dots y_N$, define

$$d_N(x^N, y^N) = \frac{1}{N} \sum_{k=1}^N d(x_k, y_k).$$

Any set $\mathcal{C} = \{y_1^N, \dots, y_M^N\}$, $y_m^N \in A^N$, of reproducing words is called a source code of block length N . Each source sequence x^N of the source $\mathbf{X} = [A^Z, P]$ is mapped into whichever code word $y_m^N \in \mathcal{C}$ minimizes $d_N(x^N, y^N)$, i.e.,

$$d_N(x^N, y_m^N) = \min_{y^N \in \mathcal{C}} d_N(x^N, y^N),$$

and the suffix m is transmitted. Hence the coding rate per source letter is $R = (\log M)/N$, and the average distortion is

$$\bar{d}_N(\mathcal{C}) = \sum_{x^N \in A^N} P^N(x^N) \min_{y^N \in \mathcal{C}} d_N(x^N, y^N).$$

The problem is how far we can reduce the rate under the condition that the average distortion keeps satisfying a given fidelity criterion, which is specified as a maximum tolerable value d for the average distortion.

The **source coding theorem with a fidelity criterion** states: Let $\mathbf{X} = [A^Z, P]$ be a memoryless source. For any specified $d \geq 0$, any $\varepsilon > 0$, and $\delta > 0$, there exists a source code \mathcal{C} with rate $R \geq R(d) + \delta$ and with sufficiently large block length N for which the average distortion satisfies

$$\bar{d}_N(\mathcal{C}) \leq d + \varepsilon,$$

where $R(d)$ is the **rate distortion function** defined by

$$R(d) = \min_{W \in \mathcal{W}(d)} I(p; W),$$

$$I(p; W) = \sum_{i=1}^n \sum_{j=1}^n p_i W(j|i) \log \frac{W(j|i)}{\sum_{i=1}^n p_i W(j|i)},$$

$$\mathcal{W}(d) = \left\{ W: \sum_{i=1}^n \sum_{j=1}^n p_i W(j|i) d(\alpha_i, \alpha_j) \leq d \right\},$$

where $W(j|i)$ denotes a conditional probability distribution referred to as the test channel, and where $I(p; W)$ is called the **mutual information**. It should be noted that $R(0) = H(\mathbf{X})$. The rate distortion function $R(d)$, which was first defined by Shannon [1, 8], is closely related to the ε -**entropy** introduced by A. N. Kolmogorov [9]. $R(d)$ is a monotonically decreasing and convex function.

The theorem was first proved by Shannon [8], and was extended by R. G. Gallager [10] to the case of stationary ergodic sources with discrete alphabets and by T. Berger [11] to stationary ergodic sources with abstract alphabets. More recently, R. G. Gray and L. D. Davisson [12] have proved source coding theorems without the ergodic assumption for stationary sources subject to a fidelity criterion. The proof was based on Rokhlin's ergodic decomposition theorem [13]. Other important source coding theorems have been obtained by F. Jelinek [14] for tree codes, A. J. Viterbi and J. K. Omura [15] for trellis codes, and Gray, D. L. Neuhoff, and D. S. Ornstein [16] for sliding block codes.

The rate distortion function for memoryless Gaussian sources subject to squared error distortion was given by Shannon [8], and that for autoregressive Gaussian sources was determined by Kolmogorov [9], M. S. Pinsker

[17], Berger [11], Gray [18], and T. Hashimoto and S. Arimoto [19].

F. Channel Coding Theory

A mathematical model for a channel over which information is transmitted is specified in terms of the set of possible inputs, the set of outputs, and a probability measure on the output events conditional on each input. The simplest channels are the noiseless ones, for which there is a one-to-one correspondence between input and output and no loss of information in transmission through the channel. The second simplest channels are **discrete memoryless channels** (DMCs) which are defined as follows: The input and the output are sequences of letters from finite alphabets (say, $\alpha_i \in A$ and $\beta_i \in B$), and the output letter at a given time depends statistically only on the corresponding input letter. That is, a DMC is characterized by a fixed conditional probability distribution $W(j|i) = W(\beta_j|\alpha_i)$ because the probability measure on the input and output sequences satisfies

$$W^N(y^N|x^N) = \prod_{k=1}^N W(y_k|x_k), \quad x_k \in A, \quad y_k \in B.$$

By $U = \{1, \dots, M\}$ we denote the set of integers each of which is assigned to each corresponding possible message from the source. A mapping $\varphi: U \rightarrow A^N$ induces a collection $\mathcal{C} = \{x_1^N, \dots, x_M^N\}$, called the **block code** with rate $R = (\log M)/N$; each element is called a code word. Only code words are transmitted over the channel. A mapping $\psi: B^N \rightarrow U$ is called the decoding. Thus, given an encoding and decoding pair $[\varphi, \psi]$, the error probability is defined by

$$P_e[\varphi, \psi] = \frac{1}{N} \sum_{m=1}^M \sum^* W^N(y^N|\varphi(m)),$$

where the summation \sum^* is taken with respect to all y^N such that $\psi(y^N) \neq m$. The **capacity** for a DMC is defined by

$$C = \max_p I(p; W) \\ = \max_p \sum_{i=1}^n \sum_{j=1}^m p_i W(j|i) \log \frac{W(j|i)}{\sum_{i=1}^n p_i W(j|i)}.$$

The fundamental theorem of channel coding theory states: Given a DMC with capacity $C > 0$, there exist a block code with rate R below capacity C , a pair $[\varphi, \psi]$, and a function $E(R) > 0$ for $0 \leq R < C$ such that the error probability satisfies

$$P_e[\varphi, \psi] < \exp\{-NE(R)\}.$$

This was first discovered by Shannon [1], and its precise proof was first given by A.

Feinstein [20]. The precise expression of $E(R)$ was subsequently given by P. Elias [21], R. M. Fano [22], and Gallager [23]. The best expression of $E(R)$, due to Gallager [23], is

$$E(R) = \max\{E_r(R), E_{ex}(R + O(N^{-1}))\},$$

where

$$E_r(R) = \max_{0 \leq \rho \leq 1} \max_p \left[-\rho R - \log \sum_j \left\{ \sum_i p_i W(j|i)^{1/(1+\rho)} \right\}^{1+\rho} \right],$$

$$E_{ex}(R) = \sup_{\rho \geq 1} \max_p \left[-\rho R - \log \sum_{i,k} p_i p_k \left\{ \sum_j \sqrt{W(j|i)W(j|k)} \right\}^{1/\rho} \right]$$

The converse of the fundamental theorem states: Given a DMC with capacity C , for any block code with rate R above C and any pair $[\varphi, \psi]$, the error probability satisfies

$$P_e[\varphi, \psi] > 1 - \exp\{-NE(R)\},$$

where $E(R)$ is a function positive for $R > C$. This was first proved by J. Wolfowitz [24], and the precise expression, found by S. Arimoto [25], is described by

$$E(R) = \max_{-1 \leq \rho \leq 0} \min_p \left[-\rho R - \log \sum_j \left\{ \sum_i p_i W(j|i)^{1/(1+\rho)} \right\}^{1+\rho} \right].$$

The fundamental theorem of coding theory and its converse imply that the capacity is a critical rate; above the capacity, information cannot be transmitted reliably through the channel. Unfortunately, there is, in general, no direct method for computing the capacity, and therefore an iterative method was proposed by Arimoto [26]. Another iterative method for computing the rate distortion function was given by R. E. Blahut [27].

A discrete channel with memory is, in general, defined by a list of probability measure $\{W_x, x \in A^Z\}$ on a \dagger measurable space $\{B^Z, \mathcal{F}_B\}$ such that for each $F \in \mathcal{F}_B$, $W_x(F)$ is a \dagger measurable function of x . A channel W is called stationary if $W_{Tx}(TF) = W_x(F)$ for all $x \in A^Z$ and all $F \in \mathcal{F}_B$. Given an input source $[A^Z, P]$ and a channel W , connecting the input to the channel induces a joint process of input and output, denoted by $[A^Z \times B^Z, PW]$ where PW is a measure on $\{A^Z \times B^Z, \mathcal{F}_{A \times B}\}$. If a joint process $[A^Z \times B^Z, PW]$ is stationary the mutual information between input and output is defined by

$$I(X; Y) = H(X) + H(Y) - H(XY).$$

A channel W is called ergodic if for every

ergodic input $[A^Z, P]$ the induced joint process $[A^Z \times B^Z, PW]$ is ergodic. The channel capacity for a discrete stationary channel is defined in various ways. The important ones are the **ergodic capacity** defined by $C_e = \sup.$ of $I(X; Y)$ with respect to all stationary ergodic sources $X = [A^Z, P]$, and the **stationary capacity** defined by $C_s = \sup.$ of $I(X; Y)$ w.r.t. all stationary sources. K. R. Parthasarathy [28] proved $C_e = C_s$ for all discrete stationary channels. In another way J. Nedoma [29] introduced the operational source/channel block coding capacity C_{scb} , which is defined as the supremum of the entropies of all admissible stationary ergodic sources in the sense that there exist source/channel block codes such that the error probability $P_e \rightarrow 0$ as block length $N \rightarrow \infty$. Nedoma [29] also pointed out an example of a stationary channel where $C_s > C_{scb}$. Hence **block coding theorems** have been proved for various channels: for **finite memory channels** by A. I. Khinchin [30], K. Takano [31], Nedoma [29], and Feinstein [32], for **\bar{d} -continuous channels** by Gray and Ornstein [33], and for **almost finite memory channels** by D. L. Neuhoff and P. C. Shields [34].

214 (XVIII.18) Insurance Mathematics

A. General Remarks

Insurance is a system in which a large number of people contribute a small precalculated amount of money (called a **premium**) to fill the economic need that arises when a person meets adversity. The amount of economic need filled by this system is called the **amount of insurance** (or **amount insured**). The **insurer** is the one who implements the system. **Actuarial mathematics** is the branch of applied mathematics that studies the mathematical basis of insurance, one of the first cases in which mathematics was successfully applied to a social question. Actuarial mathematics can be divided into two branches according to its application. The first includes the calculation of various values of each individual policy, such as premiums or reserves. The second is mainly connected with management of an insurance business and includes the study of reinsurance systems, of the maximum amount of insurance, of the contingency fund, or the analysis of profits. There is only one basic principle in actuarial mathematics, called the **principle of equivalence**. It determines the premium and reserve in each year so that the present value of future premium income of the insurer is equal to the present value of future benefits for each policy.

The basic factors of actuarial calculations are (1) probabilities of contingencies, (2) an expected rate of interest in the future (often referred to as the **assumed rate of interest**), and (3) cost of administration of the system.

Premiums are calculated using these factors and the principle of equivalence. The following is an example of the classical method of calculation for a life insurance policy with the use of “commutation symbols,” which is an old device for the convenience of calculations.

We write P for the net premium (in which the cost of administration is disregarded), P' for the gross premium, T_t for the amount of death benefits payable in the t th year after the policy is issued, E_t for the amount of survival benefits payable at the beginning of the t th year, n for the period for which the insurance is effective, and m for the period for which premiums are to be paid. Let α , β , and γ stand for three positive constants determining the initial expenses $= \alpha(T_1 \text{ or } E_1)$, the premium collection expenses $= \beta P'$, and the general expenses for maintenance $= \gamma(T_t \text{ or } E_t)$. The factor that comes into consideration next is a **model of human death and survival** (measurement).

Assume that l_x is the number of lives attaining age x , and write q_x for the probability that a life of x years will end within one year. Then d_x , the number of lives ending within one year out of l_x , is $l_x q_x$, and l_{x+1} , the number of lives remaining after one year at age $x+1$, is $l_x - d_x = l_x(1 - q_x)$. The commutation symbols commonly employed are defined as follows: Write $v = 1/(1+i)$, where i is the assumed rate of interest; then

$$D_x = l_x v^x, \quad C_x = d_x v^{x+1},$$

$$N_x = \sum_{t=0}^n D_{x+t}, \quad M_x = \sum_{t=0}^n C_{x+t}.$$

For a policy issued at an insured person's age x , the present value of the insurer's future income can be expressed as $P'(N_x - N_{x+m})/D_x$, and the present value of his future payments can be expressed as

$$\frac{1}{D_x} \left(\sum_{t=1}^n T_t C_{x+t-1} + \sum_{t=1}^{n+1} E_t D_{x+t-1} + \alpha(T_1 \text{ or } E_1) D_x + \gamma \sum_{t=0}^n (T_t \text{ or } E_t) D_{x+t-1} + \beta P'(N_x - N_{x+m}) \right).$$

By assuming that the present value of the future income is equal to the present value of the future payments, the value of the gross premium P' is obtained. (The P' obtained from the assumption $\alpha = \beta = \gamma = 0$ is denoted by P and is called the **net premium**. The difference $P' - P$ is called the **loading**.) For a policy in which benefits are payable on disability or contingencies other than death, we have only to obtain a model of contingencies and apply a similar calculation.

B. Liability Reserve

During the term of an insurance contract, it often happens that the present value of the future income is less than the present value of the future payments. If this is the case, the difference is to be held by the insurer as the **liability reserve**. The source of this fund is the past premium income plus interest. The net premium reserve, which disregards expenses, is calculated as

$$V_t = \frac{1}{D_{x+t}} \left(\sum_{r=t+1}^n T_r C_{x+r-1} + \sum_{r=t+1}^{n+1} E_r D_{x+r-1} - P(N_{x+1} - N_{x+m}) \right).$$

Between the net premium P and the net premium reserve V , we have the relation

$$P = (vV_t - V_{t-1}) + (T_t - V_t)vq_{x+t} + E_t.$$

The first term of the right-hand side of this formula is called the **savings premium**, since it is the amount left out of the premium income of the t th year and added to the reserve. The second term is called the **cost of insurance** or **risk premium** and is applied to cover the difference between the amount of insurance and that of the existing reserve in case the contingency of death arises. The third term is applied to the payment of the survival benefits (or annuities in case of an **annuity contract**). If $T_t - V_t$, the amount of risk insured by the insurer, is positive for all values of t during the period of insurance, the policy is called **death insurance**. On the other hand, if the value of $T_t - V_t$ is negative for all values of t , the policy is called **survival insurance**. If the value of $T_t - V_t$ varies between positive and negative according to the different values of t , the policy is called **mixed insurance**. If T_t is always equal to V_t , the policy constitutes mere savings. Most of the insurance policies issued today are one or another type of death insurance, while life annuity policies are a type of survival insurance. For a long time, studies have been made of the effect on premiums and reserves of changes in the three basic factors (1), (2), and (3) in Section A.

C. Risk Theory

Risk theory occupies a special position in the field of actuarial mathematics. Actuarial mathematics was first born from the theory of probability. Since the modern theory of probability based on measure theory was developed by A. N. Kolmogorov and other mathematicians (\rightarrow 342 Probability Theory), new ap-

proaches have inevitably been made to actuarial mathematics. An outstanding example is risk theory.

Risk theory can be divided into two branches. One is called **classical risk theory** (or **individual risk theory**), in which the profit or loss that may result during a certain term of an insurance contract is regarded as a \dagger random variable. Since the insurer's profit equals the sum of these random variables over all the individual contracts, various probability functions can be obtained by applying the theory of probability. The second, called **collective risk theory**, pays no attention to each individual contract but studies changes in the insurer's balance as a whole with the lapse of time. The basis of collective risk theory was given by F. Lundberg, H. Cramér, and other mathematicians.

We explain the collective risk theory following Cramér [5]. For simplicity we consider an insurer who issues no policies other than death insurance and makes no expenditures except the policy claims. Suppose that during the time interval $(t, t + \Delta t)$ contingency occurs with probability $\lambda \Delta t + o(\Delta t)$ independently of the past. We denote by $F(x)$ the \dagger distribution function of the amount to be paid by the insurer when a contingency occurs. Then the number of contingencies in $(0, t)$, $N(t)$, is a \dagger Poisson process with parameter λ , and the total expenditure of the insurer during the time interval $(0, t)$, $X(t)$, is a \dagger compound Poisson process (\rightarrow 5 Additive Processes) such that

$$E(e^{izX(t)}) = \exp \left(\lambda t \int_0^\infty (e^{izx} - 1) dF(x) \right).$$

If p is the premium income per unit time, then we have $p = \lambda \int_0^\infty x dF(x)$, because $E(X(t)) = pt$ holds by the principle of equivalence. If u denotes the initial fund of the insurer, then the fund reserved at time t , $Y(t)$, equals $u + pt - X(t)$. $Y(t)$ is a \dagger Lévy process (\rightarrow 5 Additive Processes) such that

$$\begin{aligned} E(e^{izY(t)}) \\ = \exp \left(izu + \lambda t \int_0^\infty (e^{izx} - 1 - izx) dF(x) \right). \end{aligned}$$

The probability that $Y(t) < 0$ for some time $t < \infty$ is called the **ruin probability**, which depends on the initial fund u , denoted by $\psi(u)$. This satisfies the following \dagger integral equation of Volterra type:

$$\begin{aligned} \frac{p}{\lambda} \psi(u) = \int_u^\infty Q(x) dx + \int_0^u \psi(x) Q(u-x) dx \\ (Q(x) = 1 - F(x)), \end{aligned}$$

from which one can derive an asymptotic relation $\psi(u) \sim Ce^{-Ru}$ as $u \rightarrow \infty$, where R and C

are positive constants depending only on λ and F . See [6] for recent developments in risk theory.

215 (XIX.6) Integer Programming

A. General Remarks

Integer programming, in its broadest sense, addresses itself to either minimization or maximization of a functional f over some discrete set S in \mathbf{R}^n , but it is usually understood as dealing with questions related to linear programming problems (\rightarrow 255 Linear Programming) with additional integrality conditions on the variables, namely, the problem P_0 : Minimize $\{c'x \mid Ax = b, x \geq 0, x_j \text{ an integer}, j = 1, \dots, n_1 (\leq n)\}$, where $A \in \mathbf{R}^{m \times n}$, $b \in \mathbf{R}^m$, $c \in \mathbf{R}^n$ are given data and $x = (x_1, \dots, x_n)' \in \mathbf{R}^n$ is a vector. P_0 is called a **pure integer programming problem** or an **all-integer programming problem** if $n = n_1$, and a **mixed integer programming problem** if $n_1 < n$. In particular, P_0 is called a **0-1 integer programming problem** if all the integer variables are restricted to be equal to either 0 or 1. We write

$$X^0 = \{x \in \mathbf{R}^n \mid Ax = b, x_j \geq 0, j = 1, \dots, n\},$$

$$X^I = X^0 \cap \{x \in \mathbf{R}^n \mid x_j \text{ is an integer}, j = 1, \dots, n_1\},$$

and assume for simplicity that (i) $X^I \neq \emptyset$, (ii) X^0 is bounded, and (iii) all the components of A and b are integers. P_0 arises not only as a mathematical model for an optimization problem where some of the decision variables have indivisible minimum units but also as one for many optimization problems with some logical and/or combinatorial constraints [1].

Algorithms for solving P_0 can be classified into algebraic methods and enumerative methods. Both are based upon linear programming and **relaxation** techniques [2] in which some of the constraints of P_0 are temporarily relaxed (\rightarrow 264 Mathematical Programming).

B. Cutting Plane Methods

The origin of this class of algorithms is the **fractional cutting plane algorithm** proposed in 1958 by R. E. Gomory [3], the outline of which is described as:

- (1) Let $X = X^0$.
- (2) Solve a linear programming problem: Minimize $\{c'x \mid x \in X\}$, and let \bar{x} be its \dagger optimal solution. If the \bar{x}_j are integer for all $j \leq n_1$, then stop (\bar{x} is optimal to P_0). Otherwise, go to (3).
- (3) Generate a half-space $H = \{x \in \mathbf{R}^n \mid \pi'x \geq \pi_0\}$ ($\pi \in \mathbf{R}^n, \pi_0 \in \mathbf{R}^1$), where H (i) contains X^I and (ii) does not contain \bar{x} . Return to (2) by replacing X by $X \cap H$.

Here, a linear programming problem obtained by relaxing integrality conditions is solved, and as long as $\bar{x} \notin X^I$, an inequality satisfying the two conditions (i), (ii) of (3) is introduced. Such an inequality $\pi'x \geq \pi_0$ or equality $\pi'x = \pi_0$ is called a **cut** or a **cutting plane**. Gomory devised a **Gomory cut** using (relaxed) integrality conditions on the variables, and showed that the algorithm above produces a point of X^I in finitely many steps. Some of the other algorithms using cutting planes are the **all-integer algorithm** (Gomory, 1963) and the **primal all-integer algorithm** (R. D. Young, *Operations Res.*, 16 (1968)). These algorithms, however, are generally slow and behave erratically, so that it is believed that they cannot in practice serve as general-purpose algorithms.

C. Other Algebraic Methods

Gomory [4], again in 1965, proposed a **group-theoretic approach** to P_0 . This method is based upon the following observation: Let x_B be the vector of \dagger basic variables (\rightarrow 255 Linear Programming) associated with a \dagger dual feasible basis of a linear programming problem \bar{P}_0 : Minimize $\{c'x \mid x \in X^0\}$, and let \tilde{X}^I be the set generated from X^I by relaxing the nonnegativity constraints on x_B . Then \tilde{X}^I can be shown to have a \dagger cyclic group structure, so that a **group minimization problem** P_G : minimize $\{c'x \mid x \in \tilde{X}^I\}$ can be solved as a \dagger shortest path problem on a directed graph with a special structure (\rightarrow 186 Graph Theory). If the optimal solution \tilde{x} of P_G satisfies $\tilde{x}_B \geq 0$, then it is optimal for P_0 . If, on the other hand, $\tilde{x}_B \not\geq 0$,

then a branch and bound algorithm described later can be applied for a systematic search of integer points near \tilde{x} . This algorithm is reported to produce good results when the size of the associated graph is not excessively large (G. A. Gorry et al., *Management Sci.*, 17 (1971)). Some of the other important results in this area are: (i) the theory of **subadditive cuts** (R. Gomory et al., *Math. Prog.*, 3 (1972)) and **disjunctive cuts** (E. Balas, in *Nonlinear Programming 2*, O. Mangasarian et al. (eds.), Academic Press, 1975), (ii) research on facial structures of the **integer polyhedron** $\text{co}X^I$ (convex hull of X^I) for some of the more important integer programming problems, such as that of the **corner polyhedron** $\text{co}\tilde{X}^I$ [5], knapsack polytopes (E. Balas, *Math. Prog.*, 8 (1975)), and traveling-salesman polytopes (M. Grötschel et al., *Math. Prog.*, 16 (1979)). It should be pointed out, however, that more difficulties of P_0 have been revealed rather than resolved through the intensive research in this area. Incidentally, the 0-1 integer programming problem is known to be ${}^{\dagger}NP$ -complete (\rightarrow 71 Complexity of Computations).

D. Enumerative Methods

Another large class of algorithms for solving P_0 consists of the **branch and bound methods**, first proposed by Land and Doig [6] in 1960. An outline of the improved version (R. J. Dakin, *Computer J.*, 8 (1965)) is as follows.

- (1) Let $\mathcal{P} = \{P_0\}$, $z^* = \infty$, $x^* = \text{undefined}$.
- (2) If $\mathcal{P} = \emptyset$, then stop (x^* is optimal to P_0). Otherwise, choose from \mathcal{P} the problem P_i : Minimize $\{c'x \mid x \in X_i^I\}$.
- (3) Solve \bar{P}_i : Minimize $\{c'x \mid x \in X_i\}$, in which the integrality condition is relaxed from the constraints of P_i . If \bar{P}_i has an optimal solution \tilde{x} , then go to (4). Otherwise, return to (2).
- (4) If $\tilde{x} \in X_i^I$ and $c'\tilde{x} < z^*$, then let $\tilde{x} \rightarrow x^*$, $c'\tilde{x} \rightarrow z^*$, and return to (2). If $\tilde{x} \in X_i^I$ and $c'\tilde{x} \geq z^*$, then return to (2). Otherwise, go to (5).
- (5) Choose $j \leq n_1$, for which \tilde{x}_j is not integral and generate the two **subproblems** P_j^+ : minimize $\{c'x \mid x \in X_i^I, x_j \geq [\tilde{x}_j] + 1\}$, and P_j^- : minimize $\{c'x \mid x \in X_i^I, x_j \leq [\tilde{x}_j]\}$, in both of which $[\tilde{x}_j]$ represents the largest integer not exceeding \tilde{x}_j . Let $\mathcal{P} \cup \{P_j^-, P_j^+\} \rightarrow \mathcal{P}$ and return to (2).

The best point of X^I identified during the preceding steps is denoted by x^* and called an incumbent. In summary, the branch and bound method chooses one subproblem P_i from the problem list \mathcal{P} and estimates the lower bound of its optimal objective functional value. If the lower bound is worse than the current incumbent, then P_i is discarded, whereas P_i is separated into two subproblems if no conclusion can be reached. This process

is continued until the problem list \mathcal{P} becomes empty, thereby implicitly checking all points of X^I . The above method is called an LP-based branch and bound method because linear programming techniques are employed to obtain a lower bound. The branch and bound method tends to require a large amount of storage, but many engineering improvements on the method of choosing (i) a subproblem P_i and (ii) a branching variable x_j , and several improvements of the bounding techniques, in addition to the substantial progress made in linear programming codes, enable us to solve a problem of size $n \approx 100$. In particular, an improved version of the **implicit enumeration method**, proposed by E. Balas [7] for 0-1 integer programming problems which uses logical conditions for obtaining lower bounds, is known to be able to solve rather large 0-1 integer programming problems (A. Geoffrion, *Operations Res.*, 17 (1969)).

E. Other Topics

The **partitioning algorithm** [8], in which integer variables are varied parametrically, is reported to work well for 0-1 mixed integer problems with relatively few integer variables. As people begin to realize the intrinsic difficulty of P_0 , they pay more attention to **heuristic algorithms** or approximate algorithms to obtain a good but not necessarily optimal solution. Among heuristic methods, the interior path method [9], which elaborates simple ideas such as rounding of the optimal solution of \bar{P}_0 , has been reported to work well for problems in which X^0 has a nonempty interior. Also, more emphasis is being placed on special purpose algorithms for solving practical problems, such as ${}^{\dagger}\text{set partitioning}$ and the ${}^{\dagger}\text{traveling salesman problem}$, etc. [1]. P_0 is a typical nonconvex programming problem, and no practically useful ${}^{\dagger}\text{duality theorem}$ is available. Hence it is difficult to perform sensitivity and/or post-optimality analysis. Some research in this area has emerged recently (e.g., C. J. Piper et al., *Management Sci.*, 22 (1976)), but it looks as if it will be several years before a reasonably good procedure becomes available.

216 (X.10) Integral Calculus

A. The Riemann Integral

Let $f(x)$ be a bounded real-valued function defined on an interval $[a, b]$. We shall divide this interval $I = [a, b]$ into subintervals $I_i = [x_{i-1}, x_i]$ ($i = 1, \dots, n$) by a finite number of points x_i ($a = x_0 < x_1 < \dots < x_n = b$). This division into subintervals is uniquely determined by the set $D = \{x_i\}$, called the **partition** of I . We set $M_i = \sup_{x \in I_i} f(x)$, $m_i = \inf_{x \in I_i} f(x)$, and put $\bar{\sigma}(D) = \sum_{i=1}^n M_i(x_i - x_{i-1})$, $\underline{\sigma}(D) = \sum_{i=1}^n m_i(x_i - x_{i-1})$. Considering all possible partitions D of I , we set $\int_a^b f(x) dx = \inf_D \bar{\sigma}(D)$, $\int_a^b f(x) dx = \sup_D \underline{\sigma}(D)$, which are called the **Riemann upper integral** and **Riemann lower integral** of f , respectively. If they coincide, then the common value is called the **Riemann integral** of f on $[a, b]$ and is denoted by $\int_a^b f(x) dx$. In this case, we say that f is **Riemann integrable** (or simply **integrable**) on $[a, b]$ and call f the **integrand**; a and b are called the **lower limit** and the **upper limit**, respectively. In this case, by **integrating** f from a to b we mean the process of obtaining the value $\int_a^b f(x) dx$.

Darboux's theorem: For each $\varepsilon > 0$ there exists a positive δ such that the inequalities

$$\left| \bar{\sigma}(D) - \int_a^b f(x) dx \right| < \varepsilon,$$

$$\left| \underline{\sigma}(D) - \int_a^b f(x) dx \right| < \varepsilon$$

hold for any partition D with $\delta(D) = \max_i (x_i - x_{i-1}) < \delta$. In other words, we have

$$\lim_{\delta(D) \rightarrow 0} \bar{\sigma}(D) = \int_a^b f(x) dx,$$

$$\lim_{\delta(D) \rightarrow 0} \underline{\sigma}(D) = \int_a^b f(x) dx.$$

From Darboux's theorem it follows that a necessary and sufficient condition for $f(x)$ to be integrable on $[a, b]$ is that for each positive ε there exist a positive δ such that $\delta(D) < \delta$ implies $\bar{\sigma}(D) - \underline{\sigma}(D) = \sum_{i=1}^n (M_i - m_i)(x_i - x_{i-1}) < \varepsilon$.

We call $M_i - m_i$ the **oscillation** of f on I_i and $\bar{\sigma}(D)$ and $\underline{\sigma}(D)$ the **Darboux sums**. Obviously, if f is integrable on $[a, b]$, then for each positive ε there exists a positive δ such that the following inequality holds for every partition $D = \{x_j\}$ with $\delta(D) < \delta$ and for every set of points $\xi_j \in I_j$ ($j = 1, \dots, n$):

$$\left| \sum_{j=1}^n f(\xi_j)(x_j - x_{j-1}) - \int_a^b f(x) dx \right| < \varepsilon.$$

The sum $\sum_{j=1}^n f(\xi_j)(x_j - x_{j-1})$ is often called a **Riemann sum** (or **sum of products**). A function that is continuous on $[a, b]$, or bounded and continuous except for a finite number of points in the interval, is integrable. Furthermore, a bounded function that is continuous on $[a, b]$ except for an infinite number of points x_λ is integrable if for an arbitrary positive number ε there exist a finite number of intervals I_i of which the total length is less than ε and if the set $\{x_\lambda\}$ of exceptional points is contained in $\bigcup I_i$. Generally, a necessary and sufficient condition for a bounded function defined on $[a, b]$ to be integrable is that the set of points where the function is not continuous be of \dagger measure 0 (in the sense of Lebesgue). A function that is either \dagger monotonic on $[a, b]$ (and consequently bounded) or of \dagger bounded variation is integrable. A function that is integrable on $[a, b]$ is integrable on any subinterval of $[a, b]$, the integrand being the restriction of the given function to this subinterval.

B. Basic Properties of Integrals

Let \mathbf{I} be the set of all functions integrable on $[a, b]$. If $f, g \in \mathbf{I}$, then for any numbers α, β , we have $\alpha f + \beta g \in \mathbf{I}$, $fg \in \mathbf{I}$, $\min\{f, g\} \in \mathbf{I}$, $\max\{f, g\} \in \mathbf{I}$, and $f/g \in \mathbf{I}$ provided that there exists a positive constant A such that the inequality $|g| > A$ holds. Furthermore, if $f \in \mathbf{I}$, then $|f| \in \mathbf{I}$; and if $f_n \in \mathbf{I}$ ($n = 1, 2, \dots$) and f_n converges \dagger uniformly to f , then $f \in \mathbf{I}$. Corresponding to these properties, the following formulas hold.

(1) Linearity:

$$\begin{aligned} & \int_a^b (\alpha f(x) + \beta g(x)) dx \\ &= \alpha \int_a^b f(x) dx + \beta \int_a^b g(x) dx, \end{aligned}$$

where α, β are constants.

(2) Monotonicity: If $f(x) \geq 0$, then

$$\int_a^b f(x) dx \geq 0.$$

If, further, f is continuous at a point $x_0 \in [a, b]$ and $f(x_0) > 0$, then $\int_a^b f(x) dx > 0$.

(3) Additivity with respect to intervals: If a, b , and c are points belonging to an interval on which f is integrable and $a < c < b$, then

$$\int_a^b f(x) dx = \int_a^c f(x) dx + \int_c^b f(x) dx.$$

Adopting the conventions that $\int_a^a f(x) dx = 0$ and $\int_b^a f(x) dx = -\int_a^b f(x) dx$, the additivity formula holds independently of the order of a, b , and c .

It follows from (2) that $|\int_a^b f(x) dx| \leq \int_a^b |f(x)| dx$ if $a < b$. Further, if $f_n(x)$ converges to $f(x)$ uniformly on $[a, b]$, then

$$\lim_{n \rightarrow \infty} \int_a^b f_n(x) dx = \int_a^b f(x) dx.$$

Replacing $f_n(x)$ by partial sums of a series, we obtain the following theorem: Let $\sum a_n(x)$ be a series in which each term $a_n(x)$ is integrable on an interval $[a, b]$. If the series converges uniformly on $[a, b]$, then the sum $s(x)$ is integrable on $[a, b]$, and the series is **termwise integrable**, that is,

$$\int_a^b s(x) dx = \sum_{n=1}^{\infty} \int_a^b a_n(x) dx.$$

Also, the series $\sum_{n=1}^{\infty} \int_a^x a_n(t) dt$ converges uniformly on $[a, b]$ to the integral $\int_a^x s(t) dt$. Assume that $\sum a_n(x)$ is convergent but not uniformly convergent. If all $a_n(x)$, together with $s(x) = \sum a_n(x)$, are integrable and there is a constant M independent of n such that $|s_n(x)| \leq M$ ($x \in [a, b]$) for all n , where $s_n(x)$ are partial sums, then the series is termwise integrable (C. Arzelà).

The first mean value theorem: If $f(x)$ is continuous on $[a, b]$ and $\varphi(x)$ is integrable and of constant sign on $[a, b]$, then there exists θ ($0 < \theta < 1$) such that

$$\int_a^b f(x) \varphi(x) dx = f(a + \theta(b-a)) \int_a^b \varphi(x) dx.$$

When $\varphi(x) = 1$, we have

$$\int_a^b f(x) dx = f(a + \theta(b-a))(b-a).$$

The second mean value theorem: If $f(x)$ is a positive, monotone decreasing function defined on $[a, b]$ and $\varphi(x)$ is an integrable function, then there exists η ($a < \eta \leq b$) such that

$$\int_a^b f(x) \varphi(x) dx = f(a + 0) \int_a^{\eta} \varphi(x) dx.$$

In the hypothesis of the second mean value theorem, if $f(x)$ is assumed to be monotonic but not necessarily positive, then there exists η ($a \leq \eta \leq b$) such that

$$\begin{aligned} & \int_a^b f(x) \varphi(x) dx \\ &= f(a + 0) \int_a^{\eta} \varphi(x) dx + f(b - 0) \int_{\eta}^b \varphi(x) dx. \end{aligned}$$

H. Okamura (1947) proved that the condition $a \leq \eta \leq b$ can be replaced by $a < \eta < b$.

In the case $f(x) \geq 0$ on $[a, b]$, we consider the figure F bounded by the graph of $f(x)$, the x -axis, and the lines $x = a$ and $x = b$. Then $\bar{\sigma}(D)$ and $\sigma(D)$ are areas of polygons of which one encloses F and the other is enclosed by F , as shown in Fig. 1. Hence it can be shown that the integrability of $f(x)$ in the sense of Riemann is equivalent to the measurability of F in the sense of Jordan. The Riemann integral $\int_a^b f(x) dx$ is the area of F with respect to its [†]Jordan measure.

Fig. 1

C. Relation between Differentiation and Integration

Suppose that $f(x)$ is integrable on an interval I . We fix a point a of I and consider the integration $F(x) = \int_a^x f(t) dt$, where x varies in I . The function $F(x)$ is called the **indefinite integral** of $f(x)$. In contrast with this, the integral on a fixed interval, as considered in the previous sections, is often called the **definite integral**. The indefinite integral $F(x)$ is continuous on the interval I and of bounded variation. If $f(x)$ is continuous at a point x_0 in I , then $F(x)$ is differentiable at x_0 and $F'(x_0) = f(x_0)$. In general, if a function $G(x)$ satisfies $G'(x) = f(x)$ everywhere in I , then $G(x)$ is called a **primitive function** of $f(x)$. If $f(x)$ is continu-

ous, the indefinite integral of $f(x)$ is one of the primitive functions of $f(x)$. Furthermore, if a function $G(x)$ is a primitive function of $f(x)$, then any other primitive function can be written in the form $G(x) + C$, where C is a constant, called an **integral constant**. For a continuous function $f(x)$ on $[a, b]$ and any one of its primitive functions $G(x)$, we have

$$\int_a^b f(x) dx = G(b) - G(a) = [G(x)]_a^b$$

(fundamental theorem of calculus) (\rightarrow Appendix A, Table 9). From the differentiation formulas we obtain the following integration formulas:

Integration by parts: If $f(x)$ and $g(x)$ have continuous derivatives on $[a, b]$, then

$$\int_a^b f(x)g'(x) dx = [f(x)g(x)]_a^b - \int_a^b f'(x)g(x) dx.$$

More generally, if $f(x)$ and $g(x)$ are integrable on $[a, b]$, then

$$\begin{aligned} \int_a^b g(x) \left(\int_a^x f(t) dt \right) dx \\ = \int_a^b f(x) dx \int_a^b g(x) dx - \int_a^b f(x) \left(\int_a^x g(t) dt \right) dx. \end{aligned}$$

Change of variables: If $f(x)$ is integrable on $[a, b]$ and $x = \varphi(t)$ and $\varphi'(t)$ are continuous on $[\alpha, \beta]$, where $a = \varphi(\alpha)$, $b = \varphi(\beta)$ ($a \leq \varphi(t) \leq b$), then

$$\int_a^b f(x) dx = \int_\alpha^\beta f(\varphi(t)) \varphi'(t) dt.$$

D. Improper Integrals

The concept of the integral can be generalized to the case where the integrand or the interval on which integration is accomplished is not bounded. Assume that $f(x)$ is not bounded on $[a, b]$ but is bounded and integrable on any interval $[a, b - \varepsilon]$ ($\subset [a, b]$). If $\int_{a-\varepsilon}^b f(x) dx$ has a finite limit for $\varepsilon \rightarrow 0$, the limit is denoted by $\int_a^b f(x) dx$ and is called the **improper Riemann integral** (or simply **improper integral**) of $f(x)$ on $[a, b]$. For example, if $f(x)$ is continuous on $[a, b]$ and $f(x) = O((b-x)^\alpha)$ for some α ($0 > \alpha > -1$), where O is the \dagger Landau symbol, then the improper integral $\int_a^b f(x) dx$ exists. On the other hand, if f is integrable on $[a + \varepsilon, b]$ for each $\varepsilon > 0$ but not bounded in any neighborhood of a , we can define the integral on $(a, b]$ in the same way. If f is not bounded in any neighborhood of a or b and if there exists a point c ($a < c < b$) for which the improper integrals $\int_a^c f(x) dx$ and $\int_c^b f(x) dx$ exist, then we define $\int_a^b f(x) dx = \int_a^c f(x) dx + \int_c^b f(x) dx$, which is independent of the choice of the point c . Fur-

thermore, assume that $f(x)$ is not bounded in any neighborhood of each point c_j ($j = 1, \dots, n$) ($a < c_1 < \dots < c_n < b$). Then we define

$$\begin{aligned} \int_a^b f(x) dx = \int_a^{c_1} f(x) dx + \int_{c_1}^{c_2} f(x) dx + \dots \\ + \int_{c_{n-1}}^{c_n} f(x) dx + \int_{c_n}^b f(x) dx, \end{aligned}$$

provided that all improper integrals

$$\int_a^{c_1} f(x) dx, \dots, \int_{c_n}^b f(x) dx$$

exist. Suppose that $f(x)$ is defined on $[a, b]$ and bounded outside any neighborhood of $c \in (a, b)$ but not bounded in either $[c - \varepsilon, c]$ or $[c, c + \varepsilon]$ for any $\varepsilon > 0$. It may well happen that, although neither $\lim_{\varepsilon \rightarrow 0} \int_a^{c-\varepsilon} f(x) dx$ nor $\lim_{\varepsilon' \rightarrow 0} \int_{c+\varepsilon'}^b f(x) dx$ exists (accordingly, the improper integral $\int_a^b f(x) dx$ does not exist), if we put $\varepsilon = \varepsilon'$, the limit

$$\lim_{\varepsilon \rightarrow 0} \left(\int_a^{c-\varepsilon} f(x) dx + \int_{c+\varepsilon}^b f(x) dx \right)$$

does exist. This limit is called **Cauchy's principal value** and is denoted by p.v. $\int_a^b f(x) dx$ (v.p. in French). For example, p.v. $\int_{-1}^1 (dx/x) = \lim_{\varepsilon \rightarrow 0} (\int_{-1}^{-\varepsilon} (1/x) dx + \int_{\varepsilon}^1 (1/x) dx) = 0$.

E. Integrals on Infinite Intervals

Suppose that we are given a function $f(x)$ defined on an infinite interval $[a, \infty)$ and integrable on any finite interval $[a, b]$. If $\lim_{b \rightarrow \infty} \int_a^b f(x) dx$ exists and is finite, then this limit is called the **improper integral** of f on $[a, \infty)$ and is denoted by $\int_a^\infty f(x) dx$. We define similarly $\int_{-\infty}^b f(x) dx = \lim_{a \rightarrow -\infty} \int_a^b f(x) dx$, where f is defined on $(-\infty, b]$ and integrable on any interval $[a, b]$. Furthermore, $\int_{-\infty}^\infty f(x) dx$ is, by definition, $\int_{-\infty}^c f(x) dx + \int_c^\infty f(x) dx$, which is independent of the choice of c . Suppose that $f(x)$ is integrable on $[a, b]$ for a fixed a and an arbitrary b larger than a . If $f(x) = O(x^\alpha)$ for some $\alpha < -1$, then $\int_a^\infty f(x) dx$ exists. Generally, for α, β such that $-\infty \leq \alpha < \infty$ and $-\infty < \beta \leq \infty$, if the improper integral $\int_\alpha^\beta f(x) dx$ exists, we say that the integral is **convergent**; otherwise, it is **divergent**. Improper integrals also satisfy the three basic properties of integrals (1), (2), and (3) (\rightarrow Section B). However, the existence of an improper integral of a function f on an interval I does not imply the existence of the improper integral of $|f|$ on the same interval I . For example, let f be a function determined by $f(0) = 0$, $f(x) = (1/x) \sin(1/x)$ for $0 < x \leq \pi$. Then $\int_0^\pi f(x) dx$ exists, but $\int_0^\pi |f(x)| dx$ does not. On the other hand, if the improper integral of $|f(x)|$ exists,

then the improper integral of $f(x)$ exists, and we have

$$\left| \int_{\alpha}^{\beta} f(x) dx \right| \leq \int_{\alpha}^{\beta} |f(x)| dx,$$

where $-\infty \leq \alpha < \beta \leq +\infty$. In this case, we say that f is **absolutely integrable** on the interval $[\alpha, \beta]$. Assume now that $f(x)$ is defined on $(-\infty, \infty)$ and integrable on any finite interval. If $\lim_{x \rightarrow \infty} \int_{-x}^x f(x) dx$ exists, then it is called **Cauchy's principal value** of the integral of f in $(-\infty, \infty)$.

If $f(x)$ is a monotone decreasing, positive, and continuous function defined on $[k, \infty)$ (where k is an integer), then according as $\sum_{v=k}^{\infty} f(v)$ converges or diverges, so does $\int_k^{\infty} f(x) dx$.

Suppose that a series $\sum_{n=1}^{\infty} f_n(x)$, where all the functions $f_n(x)$ ($n = 1, 2, \dots$) are defined and nonnegative on an infinite interval $[a, \infty)$, satisfies $\int_a^b (\sum_{n=1}^{\infty} f_n(x)) dx = \sum_{n=1}^{\infty} \int_a^b f_n(x) dx$ for arbitrary $b > a$. Then according as $\sum_{n=1}^{\infty} \int_a^{\infty} f_n(x) dx$ converges or diverges, so does $\int_a^{\infty} (\sum_{n=1}^{\infty} f_n(x)) dx$. When they converge, the following equality holds: $\int_a^{\infty} \sum_{n=1}^{\infty} f_n(x) dx = \sum_{n=1}^{\infty} \int_a^{\infty} f_n(x) dx$. In this theorem, if $\int_a^{\infty} \sum_{n=1}^{\infty} |f_n(x)| dx$ or $\sum_{n=1}^{\infty} \int_a^{\infty} |f_n(x)| dx$ converges, then the same conclusion as above will follow even when the $f_n(x)$ are not necessarily positive (\rightarrow Appendix A, Table 9).

F. Multiple Integrals

Suppose that $f(x, y)$ is a function defined and bounded on an interval $I = \{(x, y) | a \leq x \leq b, c \leq y \leq d\}$ in the xy -plane. Partitions $\{x_j\}$ and $\{y_k\}$ of $[a, b]$ and $[c, d]$ with $a = x_0 < x_1 < \dots < x_m = b$ and $c = y_0 < y_1 < \dots < y_n = d$ determine a "partition," denoted by D , of I into subintervals of the form $I_{jk} = \{(x, y) | x_{j-1} \leq x \leq x_j, y_{k-1} \leq y \leq y_k\}$ ($j = 1, \dots, m; k = 1, \dots, n$). Writing

$$M_{jk} = \sup_{(x, y) \in I_{jk}} f(x, y),$$

$$m_{jk} = \inf_{(x, y) \in I_{jk}} f(x, y),$$

we set

$$\bar{\sigma}(D) = \sum_{j=1}^m \sum_{k=1}^n M_{jk} (x_j - x_{j-1}) (y_k - y_{k-1}),$$

$$\underline{\sigma}(D) = \sum_{j=1}^m \sum_{k=1}^n m_{jk} (x_j - x_{j-1}) (y_k - y_{k-1}).$$

Then we obtain $\inf_D \bar{\sigma}(D) \geq \sup_D \underline{\sigma}(D)$. If $\inf_D \bar{\sigma}(D) = \sup_D \underline{\sigma}(D)$, then $f(x, y)$ is called integrable on I , and the common value is called the **double integral** of f on I and is denoted by $\iint_I f(x, y) dx dy$. Analogously, we can define **n -tuple integrals** (or **multiple integrals**) and the integrability of functions of n variables.

Let K be a bounded set in the xy -plane and

I an interval containing K . Let $\varphi(x, y)$ be the characteristic function of K defined on I , that is, φ is determined by

$$\varphi(x, y) = 1 \quad \text{for } (x, y) \in K,$$

$$\varphi(x, y) = 0 \quad \text{for } (x, y) \in I - K.$$

Replacing $f(x, y)$ by this $\varphi(x, y)$, we consider $\inf_D \bar{\sigma}(D)$ ($\sup_D \underline{\sigma}(D)$). These values can be shown to be independent of the choice of such an interval I and are called the **outer area** (**inner area**) of K , respectively. When these two values coincide, K is said to be of **definite area**, and the common value is called the **area of K** . A necessary and sufficient condition for K to be of definite area is that the outer area of the \dagger boundary of K be zero. Now consider a bounded function defined on a set K of definite area. Then, taking an interval I containing K , define an extension $\varphi(x, y)$ of $f(x, y)$ as follows:

$$\varphi(x, y) = f(x, y) \quad \text{for } (x, y) \in K,$$

$$\varphi(x, y) = 0 \quad \text{for } (x, y) \in I - K.$$

If $\varphi(x, y)$ is integrable on I , then $f(x, y)$ is called **integrable** on K , and the integral of f on K is defined by $\iint_K f(x, y) dx dy = \iint_I \varphi(x, y) dx dy$, which is independent of the special choice of I . The set K is called the **domain of integration**. Since K is of definite area, the set of boundary points of K at which $\varphi(x, y)$ is not continuous can be contained in a union of intervals whose total area can be made smaller than any preassigned positive number. Consequently, a function bounded on K and continuous at each \dagger interior point of K is integrable on K . Like integrals of functions of a single variable, multiple integrals satisfy the three basic properties of integrals (\rightarrow Section B).

G. Multiple Integrals and Iterated Integrals

Suppose that we are given a function $f(x, y)$ that is continuous on an interval $I = \{(x, y) | a \leq x \leq b, c \leq y \leq d\}$. Then, for a fixed y in $[c, d]$, the function $f(x, y)$, regarded as a function of x , can be integrated with respect to x on the interval $[a, b]$, and the integral thus obtained is a continuous function of y . The integral of the function defined on $[c, d]$, namely, $\int_c^d (\int_a^b f(x, y) dx) dy$, is called the **iterated integral** (or **repeated integral**) of $f(x, y)$ and is often written as $\int_c^d dy \int_a^b f(x, y) dx$. The following formula gives a representation of a double integral by iterated ones:

$$\begin{aligned} \iint_I f(x, y) dx dy &= \int_c^d dy \int_a^b f(x, y) dx \\ &= \int_a^b dx \int_c^d f(x, y) dy. \end{aligned}$$

More generally, $\varphi_1(x)$ and $\varphi_2(x)$ being continuous on $[a, b]$ and $\varphi_1(x) \leq \varphi_2(x)$, consider the following subset $K = \{(x, y) | a \leq x \leq b, \varphi_1(x) \leq y \leq \varphi_2(x)\}$ of the xy -plane. Suppose further that $f(x, y)$ is continuous on K . Then the following equality holds:

$$\iint_K f(x, y) dx dy = \int_a^b dx \int_{\varphi_1(x)}^{\varphi_2(x)} f(x, y) dy.$$

In the case of unbounded integrands or unbounded domains of integration, we can still define integrals under suitable restrictions. For instance, assume the following two properties: (1) There exists a sequence $\{K_n\}$ of sets, each of which is of definite area, satisfying $K_1 \subset K_2 \subset \dots$ and $K = \bigcup_{n=1}^{\infty} K_n$. (2) $f(x, y)$ is bounded and integrable on each K_n ($n = 1, 2, \dots$). If a finite limit $\lim_{n \rightarrow \infty} \iint_{K_n} f(x, y) dx dy$ exists and is independent of the choice of $\{K_n\}$, then $f(x, y)$ is called integrable on K . This limit is called the integral of $f(x, y)$ on K and is denoted by $\iint_K f(x, y) dx dy$:

$$\lim_{n \rightarrow \infty} \iint_{K_n} f(x, y) dx dy = \iint_K f(x, y) dx dy.$$

When the integral thus defined exists, we say that the integral is convergent. If a finite limit $\lim_{n \rightarrow \infty} \iint_{K_n} |f(x, y)| dx dy$ exists for some sequence $\{K_n\}$ with property (1), then f is integrable on K . Let $f(x, y)$ be continuous and nonnegative on $K = \{(x, y) | \alpha < x < \beta, \gamma < y < \delta\}$, where $-\infty \leq \alpha < \beta \leq \infty, -\infty \leq \gamma < \delta \leq \infty$. Furthermore, let $f(x, y)$ be integrable on K , and assume that the improper integral $F(x) = \int_{\gamma}^{\delta} f(x, y) dy = \lim_{c \downarrow \gamma, d \uparrow \delta} \int_c^d f(x, y) dy$ exists and converges uniformly with respect to x as $c \downarrow \gamma, d \uparrow \delta$. Then $\int_{\alpha}^{\beta} F(x) dx$ is well defined, and we have

$$\iint_K f(x, y) dx dy = \int_{\alpha}^{\beta} dx \int_{\gamma}^{\delta} f(x, y) dy.$$

In particular, if $\alpha = a, \gamma = b, \beta = \delta = \infty$, then we have

$$\int_a^{\infty} \int_b^{\infty} f(x, y) dx dy = \int_a^{\infty} dx \int_b^{\infty} f(x, y) dy.$$

H. Interchanging the Order of Differentiation and Integration

If both $f(x, y)$ and $\partial f(x, y)/\partial y$ are continuous on an interval $\{(x, y) | a \leq x \leq b, y_0 - \eta \leq y \leq y_0 + \eta\}$, then we can interchange the order of differentiation and integration as follows:

$$\frac{d}{dy} \int_a^b f(x, y) dx = \int_a^b \frac{\partial f(x, y)}{\partial y} dx \quad \text{for } y = y_0.$$

Assume further that this equality holds for

216 Ref. Integral Calculus

every $b(>a)$, the improper integral

$$\int_a^{\infty} f(x, y) dx = \lim_{b \rightarrow \infty} \int_a^b f(x, y) dx$$

converges, and the improper integral

$$\int_a^{\infty} \frac{\partial f(x, y)}{\partial y} dx = \lim_{b \rightarrow \infty} \int_a^b \frac{\partial f(x, y)}{\partial y} dx$$

converges as $b \rightarrow \infty$ uniformly for y with $|y - y_0| < \eta$. Then

$$\frac{d}{dy} \int_a^{\infty} f(x, y) dx = \int_a^{\infty} \frac{\partial f(x, y)}{\partial y} dx \quad \text{for } y = y_0.$$

Several other similar theorems are known.

Though the previous theorems are written in terms of two variables, analogous theorems hold for n variables.

I. Change of Variables in Multiple Integrals

Let G be a bounded domain of definite area in an n -dimensional Euclidean space $\mathbf{R}^n(x)$. Assume that a mapping $x \rightarrow y(x) = (y_1(x_1, \dots, x_n), \dots, y_n(x_1, \dots, x_n))$ is of class C^1 from an open set containing the closure \bar{G} of G into an n -dimensional Euclidean space $\mathbf{R}^n(y)$. We denote the image of G under this mapping by B . If $f(y_1, \dots, y_n)$ is continuous on B , then the following formula on change of variables holds:

$$\int \dots \int_B f(y_1, \dots, y_n) dy_1 \dots dy_n = \int \dots \int_G g(x_1, \dots, x_n) \left| \frac{D(y_1, \dots, y_n)}{D(x_1, \dots, x_n)} \right| dx_1 \dots dx_n,$$

where $g(x_1, \dots, x_n) = f(y_1(x_1, \dots, x_n), \dots, y_n(x_1, \dots, x_n))$ and $D(y_1, \dots, y_n)/D(x_1, \dots, x_n)$ is the

*Jacobian determinant of the mapping $y(x)$. This formula is usually utilized in the case where y_1, \dots, y_n are *functionally independent, though otherwise both sides vanish and the formula still holds. For improper integrals, a similar formula will hold under suitable restrictions, for example, if the integrals converge absolutely.

217 (XIII.30) Integral Equations

A. General Remarks

Equations including the integrals of unknown functions are called **integral equations**. The most studied ones are the **linear integral equations**, i.e., linear in unknown functions.

Let D be a domain of n -dimensional Euclidean space and $f(x)$ and $K(x, y)$ be functions defined for $x = (x_1, x_2, \dots, x_n) \in D$, $y = (y_1, y_2, \dots, y_n) \in D$. **Integral equations of Fredholm type** (or **Fredholm integral equations**) [1] are those of the forms

$$\int_D K(x, y)\varphi(y)dy = f(x), \quad (1)$$

$$\varphi(x) - \int_D K(x, y)\varphi(y)dy = f(x), \quad (2)$$

$$A(x)\varphi(x) - \int_D K(x, y)\varphi(y)dy = f(x), \quad (3)$$

where $\varphi(x)$ is an unknown function and $\int_D dy$ means the n -fold integral $\int \dots \int_D dy_1 \dots dy_n$. Equations of the forms (1), (2), and (3) are called equations of the **first**, **second**, and **third kind**, respectively. Equations of the second kind have been investigated in great detail.

Equations of the third kind, in many cases, can be reduced formally to those of the second kind. The function $K(x, y)$ is called a **kernel** (or **integral kernel**) of the integral equation.

Integral equations of Volterra type (or **Volterra integral equations**) are those of the forms

$$\int_a^x K(x, y)\varphi(y)dy = f(x), \quad (1')$$

$$\varphi(x) - \int_a^x K(x, y)\varphi(y)dy = f(x), \quad (2')$$

$$A(x)\varphi(x) - \int_a^x K(x, y)\varphi(y)dy = f(x), \quad (3')$$

where $\varphi(x)$ is an unknown function. Equations of the forms (1'), (2'), and (3') are also called equations of the **first**, **second**, and **third kind**, respectively. Integral equations of Volterra type can be regarded as integral equations of Fredholm type having kernels equal to 0 for $x < y$, but these two types of equations are usually treated separately, since they have considerably different characters.

The kernels in equations (1)–(3) and (1')–(3') are frequently written in the form $\lambda K(x, y)$ with a parameter λ , in particular when the equations are related to eigenvalue problems, which is explained in Section F.

The theory of integral equations was originated in 1823 by N. H. Abel, who investigated the relationship between time and the path of a falling body in the field of gravitation. Let $\varphi(t)$ be a quantity varying with time, which is connected by some law with its values in some time interval of the past or the future. Then the law of variation of $\varphi(t)$ can be described mathematically by an integral equation. The situation is the same even when the variable t is not time but a coordinate of the space. In this way, various problems in physics can be reduced to solutions of integral equations.

B. Relation to Differential Equations

Many problems in differential equations can be reduced to problems related to integral equations. Such reduction often makes the problems easier to handle and clarifies the nature of the solutions. For example, consider the problem of finding a solution of the ordinary second-order linear differential equation $d^2y/dx^2 + \lambda y = 0$ with the boundary condition $y(0) = y(1) = 0$ [4]. Let $d^2y/dx^2 = u(x)$. If we integrate the equation twice, change the order of integration, and make use of the boundary condition, then we have

$$y = \int_0^x (x - \xi)u(\xi)d\xi - \int_0^1 x(1 - \xi)u(\xi)d\xi,$$

from which we see that the given differential equation can be written in the form

$$u = \lambda \int_0^1 x(1-\xi)u(\xi)d\xi - \lambda \int_0^x (x-\xi)u(\xi)d\xi.$$

Decomposing the first integral on the right-hand side into the sum of an integral over $(0, x)$ and one over $(x, 1)$, and combining the integral over $(0, x)$ with the second integral on the right-hand side, we obtain a Fredholm integral equation of the first kind as follows:

$$u = \lambda \int_0^1 G(x, \xi)u(\xi)d\xi,$$

$$G(x, \xi) = \begin{cases} \xi(1-x) & (0 \leq \xi \leq x), \\ x(1-\xi) & (x \leq \xi \leq 1). \end{cases}$$

Clearly, the solution of this integral equation is equivalent to that of the original differential equation. The function G is called †Green's function for the boundary value condition $y(0) = y(1) = 0$ in the theory of boundary value problems. Differential equations of higher orders can be treated analogously (→ 315 Ordinary Differential Equations (Boundary Value Problems)). †Initial value problems of linear ordinary differential equations can be reduced to the solution of Volterra integral equations in a similar way.

As another example [5, 6], consider the †Dirichlet problem on a plane, i.e., the problem of finding a function u satisfying the conditions (i) u is †harmonic in the interior of the region D bounded by a closed curve C ($\xi = \varphi(s)$, $\eta = \psi(s)$, $0 \leq s \leq l$); (ii) $u(x, y) \rightarrow F(s)$ uniformly with respect to (x_0, y_0) as (x, y) approaches (x_0, y_0) from the inside of D , where (x_0, y_0) is an arbitrary point on C , $F(s)$ is a continuous function given on C , and s is the arc length along C . Put $f(s) = F(s)/\pi$ and

$$K(s; t) = \frac{(\psi(s) - \psi(t))\varphi'(t) - (\varphi(s) - \varphi(t))\psi'(t)}{\pi((\varphi(s) - \varphi(t))^2 + (\psi(s) - \psi(t))^2)}.$$

Then it is known that a solution u of the problem can be given in the form

$$u(x, y) = \int_0^l \mu(s) \frac{\partial}{\partial n} \log \frac{1}{r} ds,$$

where $r^2 = (\varphi(s) - x)^2 + (\psi(s) - y)^2$, n is the inner normal of C , and $\mu(s)$ is a continuous solution of the following Fredholm integral equation of the second kind:

$$\mu(s) = f(s) - \int_0^l K(s; t)\mu(t)dt.$$

We can treat the †Neumann problem similarly, i.e., the problem in which condition (ii) is replaced by (ii') $(\partial u / \partial n)(x, y) \rightarrow F(s)$ uniformly with respect to (x_0, y_0) as (x, y) approaches (x_0, y_0) from the inside of D . In the Neumann

problem, put $f(s) = F(s)/\pi$ and

$$L(s; t) = \frac{(\psi(s) - \psi(t))\varphi'(s) - (\varphi(s) - \varphi(t))\psi'(s)}{\pi((\varphi(s) - \varphi(t))^2 + (\psi(s) - \psi(t))^2)}.$$

Then we have a solution u in the form

$$u(x, y) = - \int_0^l \mu(s) \log \frac{1}{r} ds + c,$$

where $\mu(s)$ is a solution of the following Fredholm integral equation of the second kind:

$$\mu(s) = f(s) - \int_0^l L(s; t)\mu(t)dt.$$

A solution of this integral equation, however, exists when and only when $\int_0^l F(s)ds = 0$. In the expression of a solution $u(x, y)$ of the Neumann problem, c is an arbitrary additive constant, up to which a solution of the problem is determined uniquely. We can also treat partial differential equations of †elliptic type in an analogous way.

C. Integral Equations with Continuous Kernel

We describe some results for integral equations with m -dimensional independent variables, i.e., equations in which D is an m -dimensional closed domain. We assume that $K(x, y)$ and $f(x)$ are continuous in Sections D–H.

D. The Method of Successive Iteration

Among methods of solving Fredholm integral equations of the second kind, the simplest is the **method of successive iteration**, sometimes called the **method of successive approximation** [7]. In the method of successive iteration, we rewrite (2) in the form

$$\varphi(x) = f(x) + \int_D K(x, y)\varphi(y)dy$$

and replace the function $\varphi(y)$ on the right-hand side by the function

$$f(y) + \int_D K(y, z)\varphi(z)dz.$$

If we repeat the process successively, then we have

$$\varphi(x) = f(x) + \sum_{i=1}^n \int_D K_i(x, y)f(y)dy + \int_D K_{n+1}(x, y)\varphi(y)dy,$$

where

$$K_1(x, y) = K(x, y),$$

$$K_i(x, y) = \int_D K_{i-1}(x, s)K(s, y)ds.$$

The functions $K_i(x, y)$ are called the **iterated kernels**. Assume that $\sum_{n=1}^{\infty} K_n(x, y)$ converges uniformly. Then, putting

$$R(x, y) = \sum_{n=1}^{\infty} K_n(x, y), \quad (4)$$

we obtain a solution of (2) in the form

$$\varphi(x) = f(x) + \int_D R(x, y) f(y) dy. \quad (5)$$

The series (4) is called a **Neumann series**.

For a given kernel $K(x, y)$, a function $R(x, y)$ satisfying

$$K(x, y) - R(x, y) + \int_D K(x, s) R(s, y) ds = 0$$

and

$$K(x, y) - R(x, y) + \int_D R(x, s) K(s, y) ds = 0$$

is called a **resolvent** of $K(x, y)$ (in some cases $-R(x, y)$ is taken as the resolvent). If a resolvent of $K(x, y)$ exists, the solution of (2) can be given uniquely by (5). If a Neumann series converges uniformly, (4) gives a resolvent of $K(x, y)$.

If we apply a similar process to Volterra integral equations of the second kind, then we have the iterated kernels defined by

$$K_{i+1}(x, y) = \int_y^x K_i(x, s) K(s, y) ds \quad (i = 1, 2, \dots).$$

For these iterated kernels, a Neumann series defined by (4) always converges uniformly.

E. Fredholm's Method

Let D be a bounded closed domain and $K(x, y)$ a continuous kernel. A Neumann series (4) converges uniformly and gives a resolvent if $|K(x, y)|$ or the region D is sufficiently small, but otherwise it does not necessarily converge.

E. I. Fredholm [1, 7] gave a method of constructing a resolvent for the more general case. Write a kernel in the form $\lambda K(x, y)$, and put

$$K \begin{pmatrix} x_1, \dots, x_n \\ y_1, \dots, y_n \end{pmatrix} = \begin{vmatrix} K(x_1, y_1) & \dots & K(x_1, y_n) \\ \vdots & \ddots & \vdots \\ K(x_n, y_1) & \dots & K(x_n, y_n) \end{vmatrix}.$$

Define $D(\lambda)$ and $D(x, y; \lambda)$ by

$$D(\lambda) = 1 + \sum_{n=1}^{\infty} \frac{(-\lambda)^n}{n!} \int_D \dots \int_D K \begin{pmatrix} s_1, \dots, s_n \\ s_1, \dots, s_n \end{pmatrix} ds_1 \dots ds_n$$

and

$$D(x, y; \lambda) = K(x, y) + \sum_{n=1}^{\infty} \frac{(-\lambda)^n}{n!} \int_D \dots \int_D K \begin{pmatrix} x, s_1, \dots, s_n \\ y, s_1, \dots, s_n \end{pmatrix} ds_1 \dots ds_n.$$

The series in these two equations both converge uniformly and hence define entire functions of λ . The functions $D(\lambda)$ and $D(x, y; \lambda)$ are called **Fredholm's determinant** and **Fredholm's first minor** of the kernel $K(x, y)$, respectively.

For small $|\lambda|$, we have

$$\frac{D'(\lambda)}{D(\lambda)} = \sum_{n=1}^{\infty} \lambda^{n-1} \int_D K_n(s, s) ds,$$

where the $K_n(x, y)$ are iterated kernels corresponding to $K(x, y)$. Now if $D(\lambda) \neq 0$, a resolvent $\lambda R(x, y; \lambda)$ of the kernel $\lambda K(x, y)$ can be given by

$$\frac{D(x, y; \lambda)}{D(\lambda)} = R(x, y; \lambda).$$

If $D(\lambda) = 0$, some extension of the method in this section is needed. Fredholm introduced for this purpose **Fredholm's r th minor**

$$D \begin{pmatrix} x_1, \dots, x_r, \\ y_1, \dots, y_r \end{pmatrix}; \lambda$$

defined by

$$\begin{aligned} & D \begin{pmatrix} x_1, \dots, x_r, \\ y_1, \dots, y_r \end{pmatrix}; \lambda \\ &= K \begin{pmatrix} x_1, \dots, x_r \\ y_1, \dots, y_r \end{pmatrix} + \sum_{n=1}^{\infty} \frac{(-\lambda)^n}{n!} \\ & \quad \times \int_D \dots \int_D K \begin{pmatrix} x_1, \dots, x_r, s_1, \dots, s_n \\ y_1, \dots, y_r, s_1, \dots, s_n \end{pmatrix} ds_1 \dots ds_n. \end{aligned}$$

F. Eigenvalue Problems and Fredholm's Alternative Theorem

Consider a **homogeneous integral equation** of the second kind

$$\varphi(x) - \lambda \int_D K(x, y) \varphi(y) dy = 0, \quad (6)$$

where D is a bounded closed domain and $K(x, y)$ is continuous in $D \times D$. When (6) has a nontrivial solution $\varphi(x)$ for some λ , then λ is called an **eigenvalue** corresponding to the kernel $K(x, y)$, and the corresponding nontrivial solution $\varphi(x)$ is called an **eigenfunction** corresponding to the kernel $K(x, y)$. If $D(\lambda) \neq 0$, then (6) has no nontrivial solution, from which it follows that eigenvalues must be zero points of the entire function $D(\lambda)$. For an arbitrary eigenvalue λ , there is a set of linearly independent eigenfunctions corresponding to λ such that any eigenfunction corresponding to λ can be written as a linear combination of the eigenfunctions belonging to the set under consideration. Such a set of linearly independent eigenfunctions corresponding to an eigenvalue λ is called a **fundamental system** corresponding to the eigenvalue λ . The number of elements of the fundamental system is called

the **index of the eigenvalue** λ . The index of an eigenvalue is always finite. The homogeneous integral equation of the form

$$\psi(y) - \lambda \int_D K(x, y) \psi(x) dx = 0 \quad (6')$$

is called an **associated (or transposed) integral equation** of (6). The associated equation has the same eigenvalues as the original equation; moreover, the index of a common eigenvalue is the same for both equations. For any eigenvalue λ , the order of the zero point λ of the entire function $D(\lambda)$ is called the **multiplicity of the eigenvalue** λ . If an eigenvalue λ is a pole of $R(x, y; \lambda)$, then we have $p + 1 \geq r + q$, where r is the order of the pole, p is the multiplicity of λ , and q is the index of λ . In particular, if λ is a simple pole of $R(x, y; \lambda)$, we have $p = q$, namely, the multiplicity is equal to the index. An example with this particular property is the integral equation with a symmetric kernel to be discussed in Section G. For the set of eigenvalues there is no finite accumulation point even if there are infinitely many eigenvalues.

If λ is not an eigenvalue, the inhomogeneous equation

$$\varphi(x) - \lambda \int_D K(x, y) \varphi(y) dy = f(x) \quad (7)$$

can be solved uniquely for any continuous function $f(x)$. In this case we have $D(\lambda) \neq 0$, and the resolvent $R(x, y; \lambda)$ of the kernel $\lambda K(x, y)$ exists. If λ is an eigenvalue, we have $D(\lambda) = 0$, and equation (7) has a solution if and only if

$$\int_D \psi(x) f(x) dx = 0$$

for all solutions $\psi(y)$ of (6') (linearly independent solutions $\psi(y)$ are finite in number). The last statement is called **Fredholm's alternative theorem** (— 68 Compact and Nuclear Operators).

A kernel of the type

$$K(x, y) = \sum_{j=1}^n X_j(x) Y_j(y)$$

is called a **separated kernel**, **degenerate kernel**, or **Pincherle-Goursat kernel**. For such a kernel, we have $D(\lambda) = \det(\delta_{jk} - \lambda \int_a^b X_j(t) Y_k(t) dt)$, and hence we can easily obtain eigenvalues and eigenfunctions. A nondegenerate kernel can be studied using the results obtained for separated kernels, since we can regard a kernel of the general form as the limit of a sequence of separated kernels.

G. Symmetric Kernels

A kernel $K(x, y)$ is called a **symmetric kernel** if it is real and $K(x, y) = K(y, x)$. Let D be a

bounded closed domain and $K(x, y)$ be a continuous symmetric kernel. In this case the associated equation (6') clearly coincides with the original equation (6) [5, 6, 8].

Corresponding to any nontrivial symmetric kernel $K(x, y)$, there exist at least one eigenvalue and one eigenfunction. The eigenvalues are all real, and the eigenfunctions corresponding to distinct eigenvalues are mutually orthogonal. If we orthonormalize the eigenfunctions belonging to all fundamental systems and number them according to the order of increasing absolute values of the corresponding eigenvalues, then we have an orthonormal system $\{\varphi_i(x)\}$, called a **complete orthonormal system of fundamental functions** or simply a **complete orthogonal (or orthonormal) system**. If we number the eigenvalues taking their multiplicities into account and according to the order of increasing absolute values, then we have the equality

$$\sum_{i=1}^{\infty} \frac{1}{\lambda_i^2} = \int_D \int_D K^2(x, y) dx dy.$$

Corresponding to an iterated kernel $K_n(x, y)$, we have the eigenvalues $\{\lambda_i^n\}$, and we can choose the corresponding orthonormal system so that it coincides with the one corresponding to $K(x, y)$. Eigenvalues and eigenfunctions corresponding to an iterated kernel can be obtained in the following way: Put $\int_D K_n(s, s) ds = u_n$; then the following limit exists:

$$\lim_{n \rightarrow \infty} u_{2n}/u_{2n+2} = \lambda^2 < +\infty,$$

which gives an eigenvalue of the iterated kernel $K_2(x, y)$. A function $\varphi(x, y)$ defined by

$$\lim_{n \rightarrow \infty} \lambda^{2n} K_{2n}(x, y) = \varphi(x, y)$$

(uniformly convergent) gives the corresponding eigenfunction $\varphi(x, c)$ for any constant c satisfying $\varphi(x, c) \neq 0$.

Let λ^n be an eigenvalue corresponding to an iterated kernel $K_n(x, y)$ and $\varphi(x)$ be a corresponding eigenfunction. Consider the functions $\psi_j(x)$ ($j = 0, 1, \dots, n-1$) defined by

$$\psi_j(x) = \varphi(x) + \sum_{k=1}^{n-1} \varepsilon^{kj} \lambda^k \int_D K_k(x, y) \varphi(y) dy \quad (j = 0, 1, 2, \dots, n-1),$$

where ε is one of the n th primitive roots of 1. Then for at least one value of j , $\varepsilon^j \lambda$ is an eigenvalue corresponding to the kernel $K(x, y)$, and ψ_j is a corresponding eigenfunction. This relationship between eigenvalues and eigenfunctions corresponding to an iterated kernel and those corresponding to the original kernel is valid even for kernels that are not necessarily symmetric [2].

Let a kernel $K^{(n)}(x, y)$ be defined by

$$K^{(n)}(x, y) = K(x, y) - \sum_{i=1}^n \frac{\varphi_i(x)\varphi_i(y)}{\lambda_i},$$

where the λ_i ($i = 1, 2, \dots, n$) are the eigenvalues corresponding to the kernel $K(x, y)$ and the $\varphi_i(x)$ ($i = 1, \dots, n$) are the corresponding orthonormalized eigenfunctions. Then eigenvalues and eigenfunctions corresponding to $K^{(n)}(x, y)$ are those corresponding to $K(x, y)$, with the exception of $\lambda_1, \dots, \lambda_n$ and $\varphi_1(x), \dots, \varphi_n(x)$.

Let $\varphi(x)$ be any function that satisfies $\int_D (\varphi(x))^2 dx = 1$. Then the integral

$$J = \int_D \int_D K_2(x, y) \varphi(x) \varphi(y) dx dy$$

assumes the maximum value when $\varphi(x)$ is an eigenfunction corresponding to $K_2(x, y)$ with the smallest eigenvalue λ_1^2 . Let the eigenvalues λ_n of $K(x, y)$ be numbered in order of increasing absolute values, so that $|\lambda_n| \leq |\lambda_{n+1}|$. Let $\varphi(x)$ be any function satisfying

$$\int_D \psi_i(x) \varphi(x) dx = 0 \quad (i = 1, 2, \dots, n),$$

$$\int_D (\varphi(x))^2 dx = 1$$

for given functions $\psi_i(x)$ ($i = 1, \dots, n$). Then the maximum value of the integral J above is the least when the set of all linear combinations of $\{\psi_1(x), \dots, \psi_n(x)\}$ coincides with the set of all linear combinations of $\{\varphi_1(x), \dots, \varphi_n(x)\}$, and in this case the maximum of J is attained by some eigenfunction $\varphi(x)$ corresponding to $K_2(x, y)$ with the eigenvalue λ_{n+1}^2 . The results in this paragraph show that we can obtain eigenvalues by solving a variational problem concerning the integral J .

H. Expansion Theorems

Let $K(x, y)$ be a continuous symmetric kernel and $h(x)$ be a function square integrable on a bounded closed domain D . Then a function $f(x)$ such that

$$f(x) = \int_D K(x, y) h(y) dy$$

can be expanded in the form

$$f(x) = \sum_{n=1}^{\infty} c_n \varphi_n(x),$$

where $\{\varphi_i(x)\}$ is a complete orthonormal system of fundamental functions corresponding to $K(x, y)$ and

$$c_n = \int_D f(x) \varphi_n(x) dx \quad (n = 1, 2, \dots).$$

The series in the expansion of $f(x)$ converges uniformly. These facts are the content of the **Hilbert-Schmidt expansion theorem** [5, 6, 8]. By using this theorem, for a λ that is not an eigenvalue, we can obtain a solution $\varphi(x)$ of the Fredholm integral equation (7) with a symmetric kernel in the form

$$\varphi(x) = f(x) + \lambda \sum_{i=1}^{\infty} \frac{\varphi_i(x)}{\lambda_i - \lambda} \int_D f(x) \varphi_i(x) dx.$$

For $m \geq 2$, iterated kernels can be expanded in the form

$$K_m(x, y) = \sum_{i=1}^{\infty} \frac{\varphi_i(x) \varphi_i(y)}{\lambda_i^m}$$

(uniformly convergent). If $\lambda R(x, y; \lambda)$ is a resolvent of a symmetric kernel $\lambda K(x, y)$, then $R(x, y; \lambda)$ can be expanded as

$$R(x, y; \lambda) = K(x, y) + \lambda \sum_{i=1}^{\infty} \frac{\varphi_i(x) \varphi_i(y)}{\lambda_i(\lambda_i - \lambda)}.$$

If a symmetric kernel $K(x, y)$ satisfies the inequality

$$\int_D \int_D K(x, y) \varphi(x) \varphi(y) dx dy \geq 0$$

for all $\varphi(x)$, it is called a **positive (semidefinite) kernel**. If in this inequality the equality holds only for $\varphi(x) \equiv 0$, $K(x, y)$ is called a **positive definite kernel**. For a positive definite kernel, eigenvalues are all positive, and the kernel can be expanded in the form

$$K(x, y) = \sum_{i=1}^{\infty} \frac{\varphi_i(x) \varphi_i(y)}{\lambda_i}$$

(uniformly convergent). This result is called **Mercer's theorem**.

When a real continuous kernel $K(x, y)$ is not symmetric, we consider two positive kernels $\hat{K}'(x, y)$ and $\hat{K}''(x, y)$ defined by

$$\int_D K(x, s) K(y, s) ds = \hat{K}'(x, y)$$

and

$$\int_D K(s, x) K(s, y) ds = \hat{K}''(x, y).$$

The eigenvalues corresponding to these kernels are the same, and they are all positive. Let λ_i^2 ($i = 1, 2, \dots$) be these eigenvalues and $\{\varphi_i(x)\}$ and $\{\psi_i(x)\}$ be the corresponding complete orthonormal systems corresponding to \hat{K}' and \hat{K}'' , respectively. Then we have

$$\lambda_i \int_D K(y, x) \varphi_i(y) dy = \psi_i(x),$$

$$\lambda_i \int_D K(x, y) \psi_i(y) dy = \varphi_i(x).$$

Let $f(x)$ be an arbitrary function such that

$$f(x) = \int_D K(x, y)h(y)dy,$$

where $h(x)$ is a function square integrable on D . The function $f(x)$ can then be expanded in the form

$$f(x) = \sum_{i=1}^{\infty} c_i \varphi_i(x), \quad (8)$$

where

$$c_i = \int_D f(x)\varphi_i(x)dx \quad (i = 1, 2, \dots).$$

The series in the expansion (8) converges uniformly.

The Fredholm integral equation (1) of the first kind with a general kernel (i.e., a kernel that is not necessarily symmetric) has a square integrable solution $\varphi(x)$ if and only if $f(x)$ has a uniformly convergent expansion (8) and $\sum_{i=1}^{\infty} (c_i \lambda_i)^2 < +\infty$. When this condition is satisfied, equation (1) has a solution given by $\sum_{n=1}^{\infty} c_n \lambda_n \varphi_n(x)$ that converges in the sense of †mean convergence.

It should be noted that the theory concerning symmetric kernels can be extended to complex-valued **Hermitian kernels**, i.e., kernels such that $K(x, y) = \overline{K(y, x)}$. Also, we can obtain the theory in Section G and this section, concerning Fredholm integral equations with continuous kernels, by using the methods of functional analysis that treat $\int_D K(x, y)\varphi(y)dy$ as a †compact operator in the space of continuous functions (\rightarrow 68 Compact and Nuclear Operators).

I. Kernels of Hilbert-Schmidt Type

Kernels of Hilbert-Schmidt type are kernels which are square integrable in the sense of Lebesgue over $D \times D$, where D is an arbitrary domain. Most of the results mentioned in the previous section concerning integral equations with kernels continuous on bounded domains are valid also for equations with kernels of Hilbert-Schmidt type, because every operator mentioned in the previous section is also a compact operator in the space concerned, i.e., the space $L_2(D)$ [6] (\rightarrow 68 Compact and Nuclear Operators).

J. Singular Kernels

For general kernels that are not necessarily continuous, the theory described in the previous sections does not apply properly, but when an iterated kernel $K_m(x, y)$ has a resolv-

ent $R_m(x, y)$, we can find a resolvent $R(x, y)$ of $K(x, y)$ in the form

$$R(x, y) = R_m(x, y) + H_m(x, y) + \int_D R_m(x, s)H_m(s, y)ds,$$

where $H_m(x, y) = \sum_{i=1}^{m-1} K^i(x, y)$. When a kernel is of the form $\lambda K(x, y)$, the relationship between eigenvalues and eigenfunctions corresponding to an iterated kernel and those corresponding to the original kernel, which was stated in Sections G and H, is still valid for general kernels. If a kernel $K(x, y)$ is continuous for $x \neq y$ and has a singularity of the form $|x - y|^{-\alpha}$ ($0 < \alpha < 1$) on $x = y$, the iterated kernels $K_m(x, y)$ are continuous provided that $(1 - \alpha)m \geq 1$. †Green's functions of partial differential equations of elliptic type have this property.

A kernel that is not square integrable is called a **singular kernel**. An integral equation whose domain of definition is unbounded or whose kernel is singular is called a **singular integral equation** [9]. Singular integral equations have some particular properties that are not seen in ordinary integral equations, i.e., integral equations with kernels continuous in a bounded closed domain. For example [10], consider the identity

$$\begin{aligned} & \sqrt{\frac{2}{\pi}} \int_0^{\infty} \sin xy \left(\sqrt{\frac{\pi}{2}} e^{-xy} + \frac{y}{\alpha^2 + y^2} \right) dy \\ &= \sqrt{\frac{\pi}{2}} e^{-\alpha x} + \frac{x}{\alpha^2 + x^2}, \end{aligned}$$

where α is an arbitrary real number. This equality shows that for the continuous kernel $\sqrt{2/\pi} \sin xy$, 1 is an eigenvalue and $\sqrt{\pi/2} e^{-\alpha x} + x/(\alpha^2 + x^2)$ is a corresponding eigenfunction. Since α is arbitrary, the index of the eigenvalue 1 is evidently infinity. As another example, observe the equality

$$\int_{-\infty}^{\infty} e^{-|x-y|} e^{-ixy} dy = \frac{2}{1 + \alpha^2} e^{-ixx},$$

where α is an arbitrary real number. From this equality, we see that for the continuous kernel $e^{-|x-y|}$ defined on $(-\infty, \infty)$, and number $\lambda = (1 + \alpha^2)/2$ greater than or equal to 1/2 is an eigenvalue. In this example, the **spectrum**, i.e., the set of eigenvalues, is a continuum. Such a spectrum is called a **continuous spectrum**.

In applications, an important role is played by integral equations with **kernels of Carleman type**:

$$K(x, y) = G(x, y)/(y - x),$$

where $G(x, y)$ is a bounded function. In integral equations with such kernels, the integral

is taken in the sense of the \dagger Cauchy principal value [5, 9, 11, 12]. For example, the **Riemann-Hilbert problem** is the following: We are given a simple closed and smooth curve L in the complex plane and real-valued smooth functions a , b , and c defined on L , $a + ib$ never vanishing. The problem is to find a function $\varphi(z)$ which is holomorphic in the exterior of L , at most of polynomial growth at infinity, and continuous up to L with boundary value φ^+ such that $\operatorname{Re}[(a + ib)\varphi^+] = c$ on L . This problem is reduced to that of finding a function μ defined on L satisfying an integral equation

$$\mu(z) - \int_L \frac{G(z, \zeta)}{z - \zeta} \mu(\zeta) d\zeta = f(z) \quad (z \in L),$$

where G is a smooth kernel determined by $a + ib$, f is a known function depending on c , and the integral is taken in the sense of the Cauchy principal value. The integer κ defined by $\kappa = (1/\pi) \int_L d(\arg(a - ib))$ is called the **index** of this problem. The full solution of the Riemann-Hilbert problem was given by I. N. Vekua [11].

A multidimensional analog of the Cauchy principal value is the **singular integral** of A. P. Calderón and A. Zygmund (\rightarrow 251 Linear Operators). A smooth function $k(x)$ defined in \mathbf{R}^n except at $x = 0$ is called a **kernel of Calderón-Zygmund type** if $k(x)$ is positively homogeneous of order $-n$ and if its integral mean on the unit sphere is zero. Then the operator K defined by

$$Kf(x) = \lim_{\varepsilon \rightarrow 0} \int_{|y| > \varepsilon} k(y) f(x - y) dy$$

is called a Calderón-Zygmund **singular integral operator** [13]. K is a bounded linear operator in $L^p(\mathbf{R}^n)$ if $1 < p < +\infty$. If $n = 1$ and $k(x) = 1/(\pi ix)$, K is nothing but the \dagger Hilbert transformation. The pseudodifferential operator (\rightarrow 345 Pseudodifferential Operators) is an extension in some sense of the singular integral operator.

K. Systems of Integral Equations

A system of Fredholm integral equations of the second kind can always be reduced to a single equation. In fact, as is seen easily, a system of integral equations

$$\varphi_i(x) - \lambda \sum_j \int_0^1 K_{ij}(x, y) \varphi_j(y) dy = f_i(x) \quad (i = 1, 2, \dots, n)$$

can be reduced to a single equation

$$\Phi(x) - \lambda \int_0^n K(x, y) \Phi(y) dy = F(x) \quad (0 \leq x \leq n),$$

where

$$\Phi(x) = \varphi_i(x - i + 1), \quad F(x) = f_i(x - i + 1),$$

$$K(x, y) = K_{ij}(x - i + 1, y - j + 1)$$

$$(i - 1 \leq x, j - 1 \leq y \leq j; i, j = 1, 2, \dots, n).$$

A system of Volterra integral equations of the second kind can be reduced to a single equation by eliminating the unknown functions successively.

L. Integral Equations of Volterra Type

Consider a Volterra integral equation of the first kind

$$\int_a^x K(x, y) \varphi(y) dy = f(x)$$

such that $K(x, x) \neq 0$ and $K_x(x, y)$ and $f'(x)$ are continuous. If we differentiate both sides of the equation, then we have a Volterra integral equation of the second kind:

$$\varphi(x) + \int_a^x \frac{K_x(x, y)}{K(x, x)} \varphi(y) dy = \frac{f'(x)}{K(x, x)}.$$

Abel's integral equation of general form is

$$\int_0^x \frac{G(x, y)}{(x - y)^\alpha} \varphi(y) dy = f(x) \quad (0 < \alpha < 1). \quad (9)$$

If G , G_x , and f' are continuous and $G(x, x) \neq 0$, equation (9) can be reduced to the equation

$$\int_0^u H(u, y) \varphi(y) dy = \int_0^u f(x) (u - x)^{\alpha-1} dx,$$

where

$$H(u, y) = \int_y^u \frac{G(x, y) dx}{(u - x)^{1-\alpha} (x - y)^\alpha}.$$

Since $H(u, u) = (\pi/\sin \alpha\pi) G(u, u) \neq 0$, it follows that

$$\varphi(u) + \int_0^u \frac{H_u(u, y)}{H(u, u)} \varphi(y) dy = g(u), \quad (9a)$$

where

$$\begin{aligned} g(u) &= H(u, u)^{-1} \frac{d}{du} \int_0^u f(x) (u - x)^{\alpha-1} dx \\ &= H(u, u)^{-1} \left(u^{\alpha-1} f(0) \right. \\ &\quad \left. + \int_0^u (u - x)^{\alpha-1} f'(x) dx \right). \end{aligned}$$

Clearly (9a) is a Volterra integral equation of the second kind. **Abel's problem** (\rightarrow Section A) was to find the path of a falling body for a given time of descent. The problem then can be reduced to the solution of equation (9) with $G(x, y) \equiv 1$ and $\alpha = 1/2$. When $G(x, y) \equiv 1$, we

can solve equation (9) explicitly to get

$$\varphi(x) = \frac{\sin \alpha \pi}{\pi} \left(x^{\alpha-1} f(0) + \int_0^x (x-t)^{\alpha-1} f'(t) dt \right)$$

[5].

M. Nonlinear Integral Equations

When a **nonlinear integral equation** includes a parameter λ , it may happen that the parameter has a **bifurcation point**, i.e., a value λ_0 such that the number of real solutions is changed when λ varies through λ_0 taking real values. For example, consider the equation

$$\varphi(x) - \lambda \int_0^1 \varphi^2(y) dy = 1.$$

This equation has real solutions $\varphi(x) = (1 \pm \sqrt{1-4\lambda})/2\lambda$ for $\lambda \leq 1/4$ but no real solution for $\lambda > 1/4$. Hence $\lambda_0 = 1/4$ is a bifurcation point (\rightarrow 286 Nonlinear Functional Analysis).

Among nonlinear integral equations, **Hammerstein's integral equation** has been studied in detail [5, 14]. It is an equation of the form

$$\varphi(x) + \int_D K(x, y) f(y, \varphi(y)) dy = 0. \quad (10)$$

If $K(x, y)$ and $f(y, 0)$ are square integrable and $f(y, u)$ satisfies a Lipschitz condition in u with a sufficiently small coefficient, then the integral equation (10) can be solved by successive approximations. If $K(x, y)$ is a square integrable positive kernel and $\int_D |K(x, y)|^2 dy$ is bounded, then we can prove the existence and uniqueness of a solution of (10) under a condition on $f(y, u)$ weaker than a Lipschitz condition. We can prove similar results for equation (10) with a nonsymmetric kernel when $K(x, y)$ is **continuous in the mean**, that is,

$$\lim_{x' \rightarrow x} \int_D |K(x', y) - K(x, y)|^2 dy = 0,$$

$$\lim_{y' \rightarrow y} \int_D |K(x, y') - K(x, y)|^2 dx = 0.$$

A nonlinear Volterra integral equation of the form

$$\varphi(x) = f(x) + \int_a^x F(x, y, \varphi(y)) dy$$

can be solved by successive approximations if $F(x, y, u)$ and $f(x)$ are square integrable, $F(x, y, u)$ satisfies a Lipschitz condition $|F(x, y, u') - F(x, y, u'')| \leq k(x, y)|u' - u''|$ with some square integrable function $k(x, y)$, and $\int_a^x F(x, y, f(y)) dy$ is majorized by some square integrable function of x . When $F(x, y, u)$ and $f(x)$ are continuous, we can obtain theorems on the existence and uniqueness of continuous solutions and comparison theorems similar to

those for initial value problems in ordinary differential equations [16].

N. Numerical Solution

For the **numerical solution of integral equations**, we assume throughout that the functions appearing are all continuous and the solution of every equation is unique. Methods of numerical solution can be divided roughly into two classes. Methods of one class try to evaluate numerically the analytical solution described in the preceding sections, and methods of the other try to obtain a solution by transforming the problem to one that is numerically solvable.

(1) A Method Based on Numerical Quadrature.

Consider the integral equation

$$\int_a^b F(x, y, \varphi(x), \varphi(y)) dy = 0.$$

Let $a = x_1 < x_2 < \dots < x_n = b$ be points on the interval $[a, b]$ and $\varphi_1, \varphi_2, \dots, \varphi_n$ be the values of $\varphi(x)$ at x_1, x_2, \dots, x_n . By the use of numerical quadrature, we then have the following system of equations in φ_i :

$$\sum_{j=1}^n a_j F(x_i, x_j, \varphi_i, \varphi_j) = 0 \quad (i = 1, 2, \dots, n).$$

The method corresponds to that of solving ordinary differential equations by their difference equation analogs. Hence the errors involved in the solutions obtained by this method can be analyzed similarly to those in the case of numerical solution of ordinary differential equations (\rightarrow 303 Numerical Solution of Ordinary Differential Equations). If the given integral equation is a Fredholm equation of the second kind, then we have a system of linear equations in φ_i . If we apply quadrature formulas to the integral appearing in the integral equation by using the values of φ_i obtained, then we have a formula by which the solution can be evaluated directly, that is, without using an interpolation formula.

(2) A Method Utilizing Recurrence Formulas.

Let d_n and $d_n(x, y)$ be the respective coefficients of λ^n in the expansions of Fredholm's determinant $D(\lambda)$ and Fredholm's first minor $D(x, y; \lambda)$. They satisfy the recurrence formulas

$$d_n(x, y) = d_n K(x, y) + \int_a^b K(x, s) d_{n-1}(s, y) ds,$$

$$d_{n+1} = -\frac{1}{n+1} \int_a^b d_n(s, s) ds,$$

$$d_0 = 1, \quad d_0(x, y) = K(x, y).$$

By the use of these formulas, we can compute

d_n and $d_n(x, y)$ successively and hence evaluate $D(\lambda)$ and $D(x, y; \lambda)$ approximately, and by means of these recurrence formulas we can readily obtain a solution of a Fredholm equation of the second kind.

(3) A Method Utilizing Approximate Kernels.

If we replace a kernel by an approximate one in a Fredholm integral equation of the second kind, then we have an integral equation that has a solution approximately equal to the solution of the original equation. Hence if we can find an approximate kernel for which an integral equation can be solved numerically or analytically, then we can find an approximation to the desired solution by solving the modified equation. For such solutions, a method of error estimation was given by F. G. Tricomi [17].

(4) An Iterative Method. Consider the integral equation

$$\varphi(x) = \int_a^b F(x, y, \varphi(x), \varphi(y)) dy.$$

Let $\varphi_0(x)$ be an adequate function, and define $\varphi_n(x)$ successively by

$$\varphi_{n+1}(x) = \int_a^b F(x, y, \varphi_n(x), \varphi_n(y)) dy.$$

If the sequence $\{\varphi_n(x)\}$ converges, then the limit $\lim_{n \rightarrow \infty} \varphi_n(x) = \varphi(x)$ is a solution of the given equation, and hence we can obtain an approximation to a solution by calculating $\varphi_n(x)$ for some finite n . This method can be used effectively for Fredholm integral equations of the second kind with a parameter λ , provided that the absolute value of λ is smaller than the least absolute value of the eigenvalues.

(5) Variational Method. If some conditions are fulfilled, an integral equation of the form

$$G(x, \varphi(x)) + \int_a^b F(x, y, \varphi(x), \varphi(y)) dy = 0$$

can be regarded as an Euler-Lagrange equation for a variational problem

$$J[u] = \int_a^b \int_a^b E(x, y, u(x), u(y)) dx dy + \int_a^b H(x, u(x)) dx = \text{extremal.} \quad (11)$$

In this case, we can find a solution of the given integral equation numerically by solving the variational problem (11) numerically [18].

(6) Enskog's Method. Suppose that $\{\varphi_n(x)\}$ is a complete orthonormal system for the Fred-

holm integral equation (7). If we put $\psi_n(x) = \varphi_n(x) - \lambda \int_a^b K(y, x) \varphi_n(y) dy$, then from (7) we have

$$\int_a^b \varphi(x) \psi_n(x) dx = \int_a^b f(x) \varphi_n(x) dx, \quad (12)$$

and furthermore we see that $\{\psi_n(x)\}$ can be orthonormalized to yield a complete orthonormal system $\{\chi_n(x)\}$. The equality (12) then shows that the Fourier coefficients of a solution $\varphi(x)$ with respect to the system $\{\chi_n(x)\}$ can be obtained readily from the Fourier coefficients of $f(x)$ with respect to the system $\{\varphi_n(x)\}$. This method of obtaining a solution is called **Enskog's method**.

For Volterra integral equations, methods (1) and (4) can be used effectively. We usually transform equations of the first kind into equations of the second kind by differentiation and then apply the above numerical methods. This is done for the sake of securing stability of the numerical methods.

Integral Geometry

A. General Remarks

Integral geometry, in the broad sense, is the branch of geometry concerned with integrals on manifolds, but the problems considered in **integral geometry** are usually of a more limited nature. If a \dagger Lie group G acts on a \dagger differentiable manifold M as a \dagger Lie transformation group, G also acts on various figures on M , by which we mean geometric objects such as \dagger submanifolds of M , \dagger tangent r -frame bundles on M , etc. Let \mathcal{F} be a set of such figures on M invariant under G (i.e., $gF \in \mathcal{F}$ for $g \in G, F \in \mathcal{F}$). Consider the following problems: (i) to know whether any G -invariant \dagger measure μ on \mathcal{F} exists, and how to determine μ if it exists; (ii) to find the integral $\int \varphi(F) d\mu(F)$ of functions φ on \mathcal{F} with respect to the measure μ .

The term **integral geometry** was introduced by W. Blaschke, who considered the special case of problem (ii) in which $\varphi(F)$ is a function representing geometric properties of F and the integral is to be evaluated by means of the geometric invariants concerning \mathcal{F} [1]. Problems of so-called **geometric probability** (such as the problem of Buffon's needle) belong to this category. The measure μ is called the **kinetic measure** (or **kinetic density**), and $d\mu(F)$ is also denoted by dF . If \mathcal{F} has the structure of an n -dimensional differentiable manifold and the measure μ is given by a \dagger volume element ω (i.e., a positive \dagger differential form of degree n), we denote ω also by dF . Problem (i) is simple: If G acts \dagger transitively on \mathcal{F} , then $\mathcal{F} = G/H$, where H is the \dagger isotropy subgroup of G . In this case \mathcal{F} has the structure of a differentiable manifold, and if a G -invariant \dagger (Radon) measure exists, it is unique up to a multiplicative

constant. A condition for the existence of a G -invariant measure μ can be given by means of \dagger Haar measures of G and H (\rightarrow 225 Invariant Measures). We now consider some examples.

B. Crofton's Formula

Let $G(p, \theta)$ be a straight line defined by the equation $x_1 \cos \theta + x_2 \sin \theta = p$ with respect to orthogonal coordinates in a Euclidean plane. Let $n(p, \theta)$ be the number of intersections of $G(p, \theta)$ with a curve C of length L . Then we have **Crofton's formula**,

$$\int n(p, \theta) dp d\theta = 2L, \tag{1}$$

where $dp d\theta$ is the \dagger exterior product of the differential forms $dp, d\theta$ of degree 1, and the integral is extended over $p \in (-\infty, \infty)$ and $\theta \in [0, 2\pi]$.

C. Poincaré's Formula and the Principal Formula of Integral Geometry

The kinetic density dF of a figure F congruent (with the same orientation) to a fixed figure in a Euclidean plane is defined as follows: Let R be an orthogonal frame attached to F , (x_1, x_2) be the coordinates of the origin of R with respect to a fixed orthogonal frame R_0 , and θ be the angle between the first axis of R and the first axis of R_0 . If we put $dF = dx_1 dx_2 d\theta$ (exterior product), dF has the following invariance properties: (i) dF is not changed by displacements of F ; (ii) dF is not changed if instead of R we take another orthogonal frame R' attached to F .

Let two plane curves C_1, C_2 of length L_1, L_2 , respectively, be given, and suppose that C_1 is fixed and C_2 is mobile. If the number of intersections of C_2 in an arbitrary position with C_1 is finite and equal to n , then the integral of n extended over all possible positions of C_2 is given by

$$\int n dC_2 = 4L_1 L_2 \tag{2}$$

(**Poincaré's formula**). L. A. Santaló applied this result to give a solution of the \dagger isoperimetric problem (1936).

Let C_1, C_2 be two plane \dagger Jordan curves of length L_1, L_2 , respectively, and let S_1, S_2 be the areas of the domains bounded by C_1, C_2 , respectively. Suppose that C_1 is fixed and C_2 mobile, and let χ be the number of connected domains common to the domains bounded by C_1, C_2 for C_2 in an arbitrary position. Then the integral of χ extended over all possible

positions of C_2 intersecting C_1 is given by

$$\int \chi dC_2 = L_1 L_2 + 2\pi(S_1 + S_2) \quad (3)$$

(Blaschke [1]). This is the **principal formula of integral geometry**. Many formulas can be derived from it as special cases or limiting cases.

D. Generalization to Dimension n

The kinetic density of subspaces of dimension k in a Euclidean space and in a spherical space of dimension n was given by Blaschke, while the generalization of the principal formula (3) to a Euclidean space of dimension n was given by S. S. Chern, applying the methods of E. Cartan.

Let (e_1, \dots, e_n) be a positively oriented orthonormal frame with vertex A . The infinitesimal relative displacements are then given by

$$dA = \sum_{i=1}^n \omega_i e_i, \quad de_i = \sum_{j=1}^n \omega_{ij} e_j,$$

where $\omega_i = (dA, e_i)$, $\omega_{ij} = (de_i, e_j) = -\omega_{ji}$ are differential forms of degree 1 in the orthogonal coordinates of A and the $n(n-1)/2$ variables that determine e_1, \dots, e_n . For various positions of a figure, we take an orthogonal frame (A, e_1, \dots, e_n) fixed to this figure and form the exterior product

$$dK = \bigwedge_i \omega_i \bigwedge_{i < j} \omega_{ij}$$

of all the ω_i and ω_{ij} ($i < j$). This has the invariance properties (i) and (ii) of Section C and is, by definition, the kinetic density of the figure in an n -dimensional Euclidean space.

Moreover, the kinetic density of dE of k -dimensional subspaces E can be obtained by considering the orthogonal frames such that the vertex A and e_1, \dots, e_k lie on E and by forming the exterior product of the corresponding ω_α , $\omega_{\alpha\lambda}$ ($\alpha = 1, \dots, k; \lambda = k+1, \dots, n$),

$$dE = \bigwedge \omega_\alpha \bigwedge \omega_{\alpha\lambda}.$$

Let Σ be a compact orientable hypersurface of class C^2 in an n -dimensional Euclidean space, and let k_α ($\alpha = 1, \dots, n-1$) be the principal curvatures at a point on Σ . Denote by S_i the elementary symmetric form of degree i in k_α ($i = 1, \dots, n-1$), and put $S_0 = 1$. Then consider the integrals over Σ :

$$M_i = \int_\Sigma S_i dS / \binom{n-1}{i}, \quad i = 0, 1, \dots, n-1, \quad (4)$$

where dS denotes the surface element of Σ . Let D_1, D_2 be the domains bounded by two compact orientable hypersurfaces Σ_1, Σ_2 of class C^2 with volume V_1, V_2 , respectively, and let

$M_i^{(1)}, M_i^{(2)}$ be the integrals M_i defined by (4) for Σ_1, Σ_2 . If Σ_1 is fixed, Σ_2 is mobile, and the Euler-Poincaré characteristic χ of $D_1 \cap D_2$ is finite, then the generalization of (3) has the form

$$\int \chi d\Sigma_2 = I_1 \dots I_{n-1} \left(M_{n-1}^{(1)} V_2 + M_{n-1}^{(2)} V_1 + \frac{1}{n} \sum_{k=0}^{n-2} M_k^{(1)} M_{n-2-k}^{(2)} \right) \quad (5)$$

(Chern's formula), where $d\Sigma_2$ is the kinetic density of Σ_2 and I_k ($k = 1, \dots, n-1$) is the area of the unit sphere in a Euclidean space of dimension $k+1$, with the integral extended over all positions of Σ_2 intersecting Σ_1 .

Let dE be the kinetic density of the subspaces E of dimension k intersecting a compact orientable hypersurface Σ of class C^2 , and let χ be the Euler characteristic of the intersection of E with the domain bounded by Σ . The integral $\int \chi dE$ extended over all hyperplanes of dimension k intersecting Σ is proportional to M_k relative to the hypersurface Σ defined by (4). This fact generalizes (1). Further generalizations were obtained by Chern (1966).

E. Other Generalizations

For 2-dimensional spaces of constant curvature, Santaló derived formulas analogous to those in a Euclidean plane (1942–1943) and thus solved the isoperimetric problem in these spaces. In 1952, he derived a formula corresponding to (5) in n -dimensional spaces of constant curvature, following Chern's method. He investigated further integral geometry in affine, projective, and Hermitian spaces.

Chern and others obtained the results of the previous sections by Cartan's method of general moving frames and studied integral geometry in the setting of the geometry of Lie transformation groups in the sense of F. Klein (\rightarrow 137 Erlangen Program).

Chern, P. Griffiths, and others studied the value distribution theory of holomorphic mappings in several complex variables from the point of view of integral geometry (1961) (\rightarrow 21 Analytic Functions of Several Complex Variables, 124 Distribution of Values of Functions of a Complex Variable).

F. Radon Transforms

Another important topic of integral geometry is the theory of Radon transforms. Let \mathcal{F} be the set of hyperplanes $\xi(\omega, p) = \{x \in \mathbf{R}^n | (x, \omega) = p\}$ in the Euclidean space \mathbf{R}^n , where $\omega = (\lambda_1, \dots, \lambda_n)$ is a unit vector, $(x, \omega) = \sum x_i \lambda_i$, and p is real. For a function f defined in \mathbf{R}^n , define

$\hat{f}(\xi) = \hat{f}(\omega, p)$ on \mathcal{F} by

$$\hat{f}(\xi) = \int_{\xi} f(x) d_{\xi} x, \quad (6)$$

where $d_{\xi} x$ is the \dagger volume element on the hyperplane ξ such that $d_{\xi} x \wedge \sum \lambda_i dx_i = dx$, with dx the volume element of \mathbf{R}^n . Then \hat{f} is called the **Radon transform** of f . For example, if f is the \dagger characteristic function of a bounded domain V , the value $\hat{f}(\xi)$ of the Radon transform \hat{f} of f at $\xi \in \mathcal{F}$ is the volume of the section of V by ξ . Now the group G of \dagger motions of \mathbf{R}^n (the \dagger connected component of the identity of the group of isometries) acts on \mathcal{F} transitively. For every $x \in \mathbf{R}^n$, the \dagger isotropy subgroup G_x of G with respect to x acts transitively on the set $\check{x} = \{\xi \in \mathcal{F} \mid x \in \xi\}$. Since G_x is compact, there exists a unique normalized G_x -invariant measure μ on \check{x} such that $\mu(\check{x}) = 1$. For a function g on \mathcal{F} , the **conjugate Radon transform** \check{g} can now be defined by

$$\check{g}(x) = \int_{x \in \xi} g(\xi) d\mu(\xi) \quad (7)$$

as a function on \mathbf{R}^n .

The determination of \check{g} belongs to problem (ii) of integral geometry mentioned in Section A. In particular, it is important to determine $\check{g} = (\hat{f})^\sim$ for $g = \hat{f}$ and to find the relation between $(\hat{f})^\sim$ and f . These problems were solved by J. Radon for $n = 2, 3$ and by F. John in the general case. The results can be formulated as follows:

In the case of odd n , let \mathcal{S} be the space of \dagger rapidly decreasing C^∞ -functions (\rightarrow 168 Function Spaces). Let $\mathcal{S}^*(\mathcal{F})$ be the set of $g(\omega, p) \in \mathcal{S}(\mathcal{F})$ such that $\int_{-\infty}^{\infty} g(\omega, p) p^k dp = 0$ for every natural number k and every ω . For every $f \in \mathcal{S}(\mathbf{R}^n)$ and every $g \in \mathcal{S}^*(\mathcal{F})$, we then have

$$f = c\Delta^{(n-1)/2}((\hat{f})^\sim), \quad g = cL^{(n-1)/2}((\check{g})^\sim),$$

where Δ is the \dagger Laplacian in \mathbf{R}^n and $Lg(\omega, p) = d^2 g(\omega, p)/dp^2$, $c = \Gamma(n/2)^{-1} (2\pi i)^{1-n} \pi^{n/2}$.

In the case of even n , for every $f \in \mathcal{S}(\mathbf{R}^n)$, $g \in \mathcal{S}^*(\mathcal{F})$,

$$f = c_1 J_1((\hat{f})^\sim), \quad g = c_2 J_2((\check{g})^\sim),$$

where

$$J_1(f)(x) = \int_{\mathbf{R}^n} f(y) |x - y|^{1-2n} dy,$$

$$J_2(g)(\omega, p) = \int_{\mathbf{R}} g(\omega, p) |p - q|^{-n} dq.$$

These integrals are in general divergent, and they must be interpreted as regularizations defined by analytic continuation with respect to the powers of $|x - y|$ or $|p - q|$ [9].

John applied the Radon transform on \mathbf{R}^n to the study of partial differential equations in \mathbf{R}^n

A formula corresponding to \dagger Plancherel's theorem and an analog of the \dagger Paley-Wiener theorem for the Fourier transform are valid for the Radon transform (I. M. Gel'fand et al. [6]).

G. Horospheres

The theory of the Radon transform is also important in noncompact \dagger symmetric Riemannian spaces M . The connected component G of the identity in the group of isometries of M is isomorphic to the \dagger adjoint group $\text{Ad } G$ and can be considered as a linear group. Maximal \dagger unipotent subgroups of G are conjugate to each other. If N is such a subgroup, we call the \dagger orbits on M of gNg^{-1} **horospheres** on M for $g \in G$. These correspond to the hyperplanes in \mathbf{R}^n . If M is the complex upper half-plane with the \dagger hyperbolic non-Euclidean metric, the horospheres are precisely the circles tangent to the real axis and the straight lines parallel to the real axis.

The group G acts transitively on the set \mathcal{F} of horospheres on M , and we have $\mathcal{F} = G/M_0 N$. Here $G = KAN$ is an \dagger Iwasawa decomposition of G , and M_0 is the \dagger centralizer of A in K . For a horosphere $\xi \in \mathcal{F}$, let $d_{\xi} x$ be the volume element on ξ with respect to the \dagger Riemannian metric on ξ induced by the Riemannian metric on M , and define the Radon transform \hat{f} of a function f on M by (6) as a function on \mathcal{F} . For every $x \in M$, there exists a unique normalized measure on $\check{x} = \{\xi \in \mathcal{F} \mid x \in \xi\}$ invariant under the (compact) isotropy subgroup G_x of G at x ($\mu(\check{x}) = 1$). The conjugate Radon transform \check{g} of a function g on \mathcal{F} is defined by formula (7) by means of this measure μ . Then there exists an integrodifferential operator \wedge such that if \wedge^* is the adjoint operator, we have the inversion formula $f = (\wedge \wedge^* \hat{f})^\sim$ and **Plancherel's theorem**:

$$\int_M |f(x)|^2 dx = \int_{\mathcal{F}} |\wedge \hat{f}(\xi)|^2 d\xi,$$

where dx , $d\xi$ are G -invariant measures on M , \mathcal{F} , respectively, and f is an arbitrary C^∞ -function with compact support. If the \dagger Cartan subgroups of G are conjugate to each other, \wedge is a differential operator; the inversion formula can then be written in the form $f = L((\hat{f})^\sim)$ with some differential operator L on M [9].

S. Helgason applied the Radon transform on noncompact symmetric Riemannian spaces to solve differential equations on these spaces (1973).

Horospheres and Radon transforms can be defined not only for symmetric Riemannian spaces G/K , but also for various \dagger homoge-

$x_k \leq b_k, k=1, 2, \dots, n\}$ ($-\infty \leq a_k < b_k \leq \infty$) is defined by $m(I) = \prod_{k=1}^n (b_k - a_k)$. Let \mathfrak{M}_0 be the collection of all sets that can be represented as the finite union of disjoint left-open intervals, and for such expression $A = \bigcup_{j=1}^r I_j$ in \mathfrak{M}_0 define $m(A) = \sum_{j=1}^r m(I_j)$. Let $\mathfrak{M} = \mathfrak{M}_0 \cup \{\emptyset\}$ and $m(\emptyset) = 0$. Then m gives a finitely additive measure on \mathfrak{M} that is completely additive. Therefore m determines an outer measure μ^* , which in turn determines a measure μ . This μ^* is called the **Lebesgue outer measure** (or simply **outer measure**). Sets that are measurable with respect to μ^* are said to be **Lebesgue measurable** (or simply **measurable**), and the measure μ is called the (n -dimensional) **Lebesgue measure** (or simply **measure**). Every interval is measurable, and its measure coincides with its volume. Open sets, closed sets, and Borel sets are all measurable. More generally, suppose that an outer measure μ^* defined on a metric space X with a metric d satisfies the condition: If $d(A, B) > 0$, then $\mu^*(A \cup B) = \mu^*(A) + \mu^*(B)$. Then every closed subset of X is μ^* -measurable, and therefore so is every Borel subset. Here $d(A, B) = \inf\{d(a, b) | a \in A, b \in B\}$ denotes the distance between the two sets A and B . A measure μ defined on the class of all Borel subsets of a topological space X is called a **Borel measure**. The cardinality of the set of all Lebesgue measurable subsets of \mathbf{R}^n is 2^c , while the cardinality of the class of Borel sets is c (here c is the cardinal number of the t continuum, i.e., the cardinal number of \mathbf{R}). Therefore there exists a Lebesgue measurable set that is not a Borel set. It follows immediately from the definition that the Lebesgue measure is K -regular, so for every Lebesgue measurable set A we can find an $^tF_\sigma$ -set B and a $^tG_\delta$ -set C such that $B \subset A \subset C$ and $\mu(C - B) = 0$.

Historically, for a bounded subset A of \mathbf{R}^n , C. Jordan defined $\bar{m}(A)$ to be the infimum of all possible values $m(B)$, where $B \in \mathfrak{M}$ and $B \supset A$, and $\underline{m}(A)$ to be supremum of all possible values $m(B)$, where $B \in \mathfrak{M}$ and $B \subset A$. He called $\bar{m}(A)$ the **outer volume** of A and $\underline{m}(A)$ the **inner volume** of A (in the case of \mathbf{R}^2 , the **outer area** and **inner area**, respectively). When $\bar{m}(A) = \underline{m}(A)$, A is called **Jordan measurable**, and this common value is defined to be the **Jordan measure** (**Jordan content**) of A . Jordan measure is only finitely additive, and was found to be unsatisfactory in many respects. It was Lebesgue who modified this notion and introduced completely additive measures. Jordan measurable sets are always Lebesgue measurable.

Using the t axiom of choice, a set that is not Lebesgue measurable can be constructed (G. Vitali). For example, a set obtained by choosing exactly one element from each coset of the additive group of all rationals in the addi-

tive group of the reals is not measurable [3, pp. 67–70].

H. Product Measure

When two σ -finite complete measures μ_X and μ_Y are defined on completely additive classes \mathfrak{B}_X and \mathfrak{B}_Y on X and Y , respectively, an element C belonging to the smallest finitely additive class \mathfrak{R} in the Cartesian product that contains $\{A \times B | A \in \mathfrak{B}_X, B \in \mathfrak{B}_Y\}$ can be represented as a finite disjoint union $C = \bigcup_{j=1}^n (A_j \times B_j)$ ($A_j \in \mathfrak{B}_X, B_j \in \mathfrak{B}_Y$). If we define $v(C) = \sum_{j=1}^n \mu_X(A_j)\mu_Y(B_j)$ (here we agree to put $0 \cdot \infty = 0$), then this value is independent of the way the set C is represented, and v defines a completely additive measure on \mathfrak{R} . By extending v by means of Hopf's extension theorem, we obtain a (complete) measure space, called the **(complete) product measure space** obtained from the measure spaces $(X, \mathfrak{B}_X, \mu_X)$ and $(Y, \mathfrak{B}_Y, \mu_Y)$. The measure obtained in this way on the space $X \times Y$ is called the **product measure** of μ_X and μ_Y and is denoted by $\mu_X \times \mu_Y$. If we denote by \mathfrak{M}_p the class of all Lebesgue measurable subsets of the p -dimensional Euclidean space \mathbf{R}^p and by m_p the p -dimensional Lebesgue measure, then the (complete) product measure space of $(\mathbf{R}^p, \mathfrak{M}_p, m_p)$ and $(\mathbf{R}^q, \mathfrak{M}_q, m_q)$ is $(\mathbf{R}^{(p+q)}, \mathfrak{M}_{p+q}, m_{p+q})$. The product measure space of any finite number of measure spaces $(X_i, \mathfrak{B}_i, \mu_i)$ ($i = 1, \dots, n$) is defined similarly.

Let X_λ ($\lambda \in \Lambda$) be spaces with an index set of arbitrary cardinality. For the product space $X = \prod_{\lambda \in \Lambda} X_\lambda$, an n -**cylinder set**, or simply a **cylinder set**, is a set of the form $A \times \prod_{\lambda \notin \{\lambda_1, \dots, \lambda_n\}} X_\lambda$ ($A \subset X_{\lambda_1} \times \dots \times X_{\lambda_n}$). If a finitely additive class \mathfrak{A}_λ is given for each X_λ , the class of all subsets that can be represented as the union of a finite number of cylinder sets of the form $A_1 \times A_2 \times \dots \times A_n \times \prod_{\lambda \notin \{\lambda_1, \dots, \lambda_n\}} X_\lambda$ ($A_j \in \mathfrak{A}_{\lambda_j}, j = 1, 2, \dots, n$) is a finitely additive class in the space X .

When each \mathfrak{A}_λ is completely additive, the completely additive class \mathfrak{A} generated by this finitely additive class is called the **product** of the completely additive classes \mathfrak{A}_λ and is denoted by $\prod_{\lambda \in \Lambda} \mathfrak{A}_\lambda$. When a measure space $(X_\lambda, \mathfrak{B}_\lambda, \mu_\lambda)$ with $\mu_\lambda(X_\lambda) = 1$ is given for $\lambda \in \Lambda$, a measure μ can be defined in the following way on the completely additive class $\mathfrak{B} = \prod_{\lambda \in \Lambda} \mathfrak{B}_\lambda$ in the product space X : To begin with, for a cylinder set of the form $A_1 \times \dots \times A_n \times X'$ (here $A_j \in \mathfrak{B}_{\lambda_j}$ and $X' = \prod_{\lambda \notin \{\lambda_1, \dots, \lambda_n\}} X_\lambda$), we define $\mu(A_1 \times \dots \times A_n \times X') = \mu_{\lambda_1}(A_1) \dots \mu_{\lambda_n}(A_n)$. If we extend μ to the finitely additive class \mathfrak{C} consisting of all sets that can be represented as the finite union of such cylinder sets, then this extension gives a completely additive measure on \mathfrak{C} , and therefore, by Hopf's extension theorem, there exists a unique extension to a mea-

sure μ on \mathfrak{B} , and μ satisfies $\mu(X) = 1$. We denote this μ by $\mu = \prod_{\lambda \in \Lambda} \mu_\lambda$.

I. Radon Measure

Let X be a * locally compact Hausdorff space, \mathfrak{B} the topological σ -algebra on X , and $C_0(X)$ the real linear space of all real-valued continuous functions f on X having * compact support (i.e., the closure of the set $\{x | f(x) \neq 0\}$ is compact). A (real) * linear functional ϕ defined on $C_0(X)$ is called a **positive Radon measure** if $\phi(f) \geq 0$ whenever $f \geq 0$. For such a functional ϕ there corresponds a Borel measure μ on X for which $\phi(f) = \int_X f d\mu$ holds for every $f \in C_0(X)$. Lebesgue measure m_n is regarded as a positive Radon measure on \mathbf{R}^n . If X is σ -compact (i.e., X can be represented as the countable union of compact sets), then the property $\phi(f) = \int_X f d\mu$ for all $f \in C_0(X)$ defines the measure μ uniquely on the class of Borel sets of X . A linear functional on $C_0(X)$ that can be written as the difference of two positive Radon measures is called a **Radon measure**. For a linear functional ϕ defined on $C_0(X)$ to be a Radon measure, it is necessary and sufficient that for an arbitrary $f \in C_0(X)$, the set $\{\phi(g) | |g| \leq |f|, g \in C_0(X)\}$ be bounded. Equivalently, it is necessary and sufficient that the restriction of ϕ to the subspace of all functions in $C_0(X)$ having their support in a fixed compact subset of X must be continuous with respect to the * topology of uniform convergence. Therefore, if X is compact, an arbitrary continuous linear functional on $C(X)$ is a Radon measure. L. Schwartz investigated Radon measures on spaces that are not locally compact [6].

J. Measurable Functions

When a completely additive class \mathfrak{B} on a space X is given, a function f defined on a \mathfrak{B} -measurable set E and taking real (and possibly $\pm\infty$) values is called a **\mathfrak{B} -measurable function** on E if for an arbitrary real number α , the set $\{x | f(x) > \alpha\}$ is \mathfrak{B} -measurable. The condition $f > \alpha$ may be replaced by $f \geq \alpha$, $f < \alpha$, $f \leq \alpha$. A function f can also be defined to be \mathfrak{B} -measurable if the * inverse image under f of any Borel set is \mathfrak{B} -measurable. When f and g are \mathfrak{B} -measurable, so are $af + bg$ (a, b constants), $f \cdot g$, f/g , $\max(f, g)$, $\min(f, g)$, $|f|^p$ (p a constant), whenever they are well defined. The superior and inferior limits of a sequence of \mathfrak{B} -measurable functions are also \mathfrak{B} -measurable. In a complete product measure space of two σ -finite measure spaces, a function $f(x, y)$ may fail to be measurable as a function of two variables even if it is measurable with respect

to each of the variables x and y separately. For example, let \mathfrak{F} be the class of all closed subsets F of \mathbf{R}^2 satisfying $m_2(F) > 0$, $F \subset [0, 1] \times [0, 1]$. Using the fact that the cardinality of \mathfrak{F} does not exceed the cardinal number of the continuum, we can prove by * transfinite induction that the elements of \mathfrak{F} can be indexed as F_ξ , $\bar{\xi} < \bar{c}$, $\bar{\xi}$ being the cardinality of ξ , and that for every $F_\xi \in \mathfrak{F}$ we can pick two points $z_\xi = (x_\xi, y_\xi)$, $z'_\xi = (x'_\xi, y'_\xi)$ in such a way that if $F_\xi \neq F_\eta$, then $x_\xi, x'_\xi, x_\eta, x'_\eta$ are all distinct and $y_\xi, y'_\xi, y_\eta, y'_\eta$ are all distinct. Furthermore, we can prove that the set E consisting of all such z_ξ is not measurable. Therefore, denoting the characteristic function of the set E by $f(x, y)$, $f(x, y)$ is not measurable; but if we fix x (resp. y), then as a function of y (resp. x), $f(x, y)$ is measurable, since $f(x, \cdot)$ (resp. $f(\cdot, y)$) is always 0 except possibly at one point. If \mathfrak{B} is the class of all Lebesgue measurable sets or the class of all Borel sets, then a \mathfrak{B} -measurable function is called a **Lebesgue measurable function** (or simply **measurable function**) or a **Borel measurable function**, respectively.

In Euclidean space, the class of all Borel measurable functions coincides with the class of all Baire functions, and an arbitrary Lebesgue measurable function is equal almost everywhere to a Baire function of at most the second class. For a function f that is finite almost everywhere on a Lebesgue measurable set E to be Lebesgue measurable, it is necessary and sufficient that for an arbitrary $\varepsilon > 0$ we can find a closed subset F such that $m(E - F) < \varepsilon$ and f is continuous on F (**Luzin's theorem**).

If a sequence $\{f_n\}$ of \mathfrak{B} -measurable functions on a measure space (X, \mathfrak{B}, μ) converges almost everywhere to f on a set E with $\mu(E) < \infty$, then for an arbitrary $\varepsilon > 0$ we can find a set F ($F \subset E$, $F \in \mathfrak{B}$) such that $\mu(E - F) < \varepsilon$ and f_n converges uniformly on F . If $X = \mathbf{R}^n$ and \mathfrak{B} is either the class of Borel sets or the class of Lebesgue measurable sets, then the set F can be chosen to be a closed set (**Egorov's theorem**).

For a finite measurable function $f(x)$ defined on the real line, there exists a sequence $\{h_n\}$ such that $\lim_{n \rightarrow \infty} f(x + h_n) = f(x)$ almost everywhere (H. Auerbach).

The functional equation $f(x + y) = f(x) + f(y)$ has infinitely many nonmeasurable solutions (G. Hamel; — 388 Special Functional Equations).

Let \mathfrak{A}_i , $i = 1, 2$, be σ -algebras on X_i , $i = 1, 2$, respectively. A mapping $f: X_1 \rightarrow X_2$ is said to be measurable $\mathfrak{A}_1/\mathfrak{A}_2$ if $f^{-1}(A_2) \in \mathfrak{A}_1$ for every $A_2 \in \mathfrak{A}_2$. When \mathfrak{A}'_2 generates \mathfrak{A}_2 , $f: X_1 \rightarrow X_2$ is measurable $\mathfrak{A}_1/\mathfrak{A}_2$ if $f^{-1}(A'_2) \in \mathfrak{A}_1$ for every $A'_2 \in \mathfrak{A}'_2$. For example, a mapping $f: \mathbf{R}^1 \rightarrow \mathbf{R}^1$ is Borel (Lebesgue) measurable if and only if

f is measurable $\mathfrak{B}^1/\mathfrak{B}^1(\mathfrak{M}_1/\mathfrak{B}^1)$, where \mathfrak{B}^1 and \mathfrak{M}_1 denote the Borel subsets and the Lebesgue measurable subsets of \mathbf{R}^1 . Measurability of mappings is preserved by compositions, namely, if $f: X_1 \rightarrow X_2$ and $g: X_2 \rightarrow X_3$ are measurable $\mathfrak{A}_1/\mathfrak{A}_2$ and $\mathfrak{A}_2/\mathfrak{A}_3$, respectively, then $g \circ f: X_1 \rightarrow X_3$ is measurable $\mathfrak{A}_1/\mathfrak{A}_3$. If the projection $\pi_a: \prod_{i \in I} X_i \rightarrow X_a$ is measurable, then $\prod_{i \in I} \mathfrak{A}_i/\mathfrak{A}_a$. Since $\pi_i^{-1}(A_i)$ ($i \in I, A_i \in \mathfrak{A}_i$) generate $\prod_{i \in I} \mathfrak{A}_i$, a mapping $f: X \rightarrow \prod_{i \in I} X_i$ is measurable $\mathfrak{A}/\prod_{i \in I} \mathfrak{A}_i$ if $\pi_i \circ f: X \rightarrow X_i$ is measurable $\mathfrak{A}_i/\mathfrak{A}$ for every $i \in I$, where \mathfrak{A} is a σ -algebra on X .

K. Image Measures

Let μ be a regular measure on a measurable space (X, \mathfrak{B}_X) , i.e., the completion of a measure on \mathfrak{B}_X . Then every mapping $f: X \rightarrow Y$ measurable $\mathfrak{B}_X/\mathfrak{B}_Y$ induces a σ -algebra on Y :

$$\mathfrak{B} = \{B \subset Y \mid f^{-1}(B) \text{ is } \mu\text{-measurable}\},$$

and a measure on \mathfrak{B} :

$$\nu(B) = \mu(f^{-1}(B)).$$

The measure ν is called the **image measure** of μ under the mapping f ; this is denoted by μf^{-1} or $f_*\mu$. Obviously, $\nu(Y) = \mu(X)$, and ν is complete. Although \mathfrak{B} includes \mathfrak{B}_Y by virtue of the measurability of f , ν is not regular in general. However, ν is regular if μ is a bounded measure and if both (X, \mathfrak{B}_X) and (Y, \mathfrak{B}_Y) are analytic measurable spaces (\rightarrow 22 Analytic Sets I). Therefore the image measure of a regular probability measure under a measurable mapping is also a regular probability measure in practically all useful cases.

L. Related Topics

(i) **Integration.** For a nonnegative measurable function $f(x)$ on (X, \mathfrak{B}, m) , we can define the integral of $f(x)$ on a set $E \in \mathfrak{B}$, denoted by $\int_E f(x) \mu(dx)$, $\int_E f(x) d\mu(x)$, $\int_E f d\mu$, or $\int_E f$. For a real measurable function $f(x)$, the integral is defined to be equal to $\int_E f^+ d\mu - \int_E f^- d\mu$, if at least one of these integrals is finite, where f^+ and f^- are the positive and negative parts of f (\rightarrow 221 Integration Theory B).

(ii) **Fubini's theorem for measures.** Let (X, \mathfrak{B}, μ) be the complete product measure space of $(X_i, \mathfrak{B}_i, \mu_i)$ ($i = 1, 2$), where both μ_1 and μ_2 are σ -finite and complete. For $E \in \mathfrak{B}$ we define the sections $E(x_1)$ and $E(x_2)$ by

$$E(x_1) = \{x_2 \mid (x_1, x_2) \in E\},$$

$$E(x_2) = \{x_1 \mid (x_1, x_2) \in E\}.$$

Then we have $E(x_1) \in \mathfrak{B}_2$ for almost all $(\mu_1)x_1 \in$

X_1 , $E(x_2) \in \mathfrak{B}_1$ for almost all $(\mu_2)x_2 \in X_2$, and

$$\begin{aligned} \mu(E) &= \int_{X_1} \mu_2(E(x_1)) \mu_1(dx_1) \\ &= \int_{X_2} \mu_1(E(x_2)) \mu_2(dx_2) \end{aligned}$$

(\rightarrow 221 Integration Theory E).

(iii) **The Radon-Nikodym theorem and the Lebesgue decomposition theorem for measures.**

Let μ and ν be σ -finite measures on (X, \mathfrak{B}) . If $\mu(E) = 0$ implies $\nu(E) = 0$, then ν is said to be **absolutely continuous** with respect to μ , denoted by $\nu \ll \mu$. $\nu \ll \mu$ if and only if ν is expressible in the form $\nu(E) = \int_E f d\mu$, where f is a nonnegative \mathfrak{B} -measurable function (the **Radon-Nikodym theorem**). Such an f is uniquely determined up to μ -measure 0 and is called the **Radon-Nikodym derivative** of ν with respect to μ , denoted by $d\nu/d\mu$. The concept opposite to absolute continuity is singularity. ν is said to be **singular** with respect to μ if there exists an $E \in \mathfrak{B}$ such that $\nu(E^c) = \mu(E) = 0$. If μ and ν are two arbitrary σ -finite measures, then ν is expressible uniquely as the sum of an absolutely continuous measure ν_1 and a singular measure ν_2 with respect to μ (**Lebesgue decomposition theorem**) (\rightarrow 221 Integration Theory D, 380 Set Functions C).

(iv) **Invariant Measures.** Let (X, \mathfrak{B}) be a measurable space and G a group of Borel isomorphic mappings from (X, \mathfrak{B}) to itself. A measure μ on (X, \mathfrak{B}) is said to be **invariant** under G if $\mu(E) = \mu(g^{-1}(E))$ for every $E \in \mathfrak{B}$ and every $g \in G$. For example, the Lebesgue measure m on $(\mathbf{R}^n, \mathfrak{B}^n)$ is invariant under the group of congruent transformations (\rightarrow 225 Invariant Measures).

(v) **The Lebesgue-Stieltjes measure.** Let f be a right continuous monotone increasing function on \mathbf{R} . Then there exists a unique measure μ on $(\mathbf{R}, \mathfrak{B}^1)$ such that $\mu((a, b]) = f(b) - f(a)$ for $a < b$. This measure is called the **Lebesgue-Stieltjes measure** induced by f (\rightarrow 166 Functions of Bounded Variation B).

(vi) **Baire measurable functions and universally measurable functions.** Let $f(x)$ be a real-valued function defined on a topological space X . If for every open set O the inverse image $f^{-1}(O)$ has the \dagger Baire property (resp. is measurable with respect to the completion of any σ -infinite \dagger Borel measure on X), then f is said to be **Baire measurable** (resp. **universally measurable** or **absolutely measurable**). Universally measurable functions can be defined similarly on a measurable space.

(vii) **Disintegration.** Let (S, \mathfrak{S}) and (T, \mathfrak{T}) be standard measurable spaces, ν a σ -finite measure on (S, \mathfrak{S}) , and $p: S \rightarrow T$ a ν -measurable mapping. If the image measure $\mu = \nu f^{-1}$ is σ -finite, there exists a unique family of measures

$\{v_t, t \in T\}$ on (S, \mathfrak{S}) such that (1) $t \mapsto v_t(E)$ is universally measurable for every $E \in \mathfrak{S}$, (2) v_t is concentrated on $p^{-1}(t)$ for almost every t with respect to μ , and (3) the following equality holds:

$$v(E) = \int_T \mu(dt) v_t(E), \quad E \in \mathfrak{S}.$$

This expression is called the **disintegration** of v with respect to μ . Every v -measurable function f on S is v_t -measurable for almost every t with respect to μ , and the integral of f is expressible in the form of iterated integrals as follows:

$$\int_S f(s) v(ds) = \int_T \mu(dt) \int_S f(s) v_t(ds).$$

This corresponds to Fubini's theorem on product measures. When v is a probability measure on (S, \mathfrak{S}) , $p(s)$ is regarded as a (T, \mathfrak{T}) -valued random variable on (S, \mathfrak{S}, v) , and v_t is the conditional probability measure under the condition $p(s) = t$. (\rightarrow 342 Probability Theory E. For disintegration of measures on a topological space \rightarrow [3, ch. 9].)

271 (XX.4) Mechanics

A. Newton's Three Laws of Motion

The study of laws governing the motion of bodies began with the laws of falling bodies, of which the first exact formulation was made by Galileo. But the general relationship between force and acceleration was first described by †Newton, who established **Newton's three laws of motion**; the mechanics based on them is **Newtonian mechanics**. Newton expounded

these laws in his famous book *Principia mathematica philosophiae naturalis* (1686–1687), where the law of gravitation and its application, problems of fluid motion, motions of the planets in the solar system, etc., were systematically treated.

Newton's first law. A body continues its state of rest or uniform motion in a straight line unless it is compelled to change that state by external action (i.e., force). This is also called the **law of inertia**.

Newton's second law. The rate of change of momentum is proportional to force and is in the direction in which the force acts. Here, **momentum** is defined as the product mv of the mass m and the velocity v . This law can be expressed as $d(mv)/dt = F$, where F is the force expressed in an appropriately chosen system of units. Since dv/dt is the acceleration a , the law takes the form $ma = F$, when the mass is constant. These equations are called **equations of motion**. The second law is often simply called the **law of motion**.

Newton's third law. When two bodies 1 and 2 in the same system interact, the force exerted on body 1 by body 2 is equal and opposite in direction to that exerted on body 2 by body 1. This law is called the **law of action and reaction**, or simply the **law of reaction**.

Various attempts at a rigorous axiomatization of Newtonian mechanics have been made, beginning with E. Mach's work. At the beginning of the 20th century, it was found that Newtonian mechanics requires modification when bodies travel at speeds approaching the speed of light or when it is applied to physical systems of molecular size or smaller. These modifications led to the establishment of the theory of †relativity and †quantum mechanics. In contrast to these later theories, Newtonian mechanics is called **classical mechanics**.

B. Newton's Law of Gravitation

Kepler discovered the following three laws for the motion of planets around the sun (valid within the accuracy in observation available at the time):

Kepler's first law. The orbit of a planet is an ellipse with the sun at one of its foci.

Kepler's second law. The area swept per unit time by the straight line segment joining the planet and the sun is independent of the position of the planet in its orbit.

Kepler's third law. The square of the period (the time needed for the planet to go around the orbit once) is proportional to the cube of the major axis of the orbit.

From these empirical laws, Newton deduced his **law of universal gravitation**: Between any

pair of point particles, with masses m_1 and m_2 and at a distance r , there arises an attractive force along the line joining the two points; the magnitude of this force is given by $F = Gm_1m_2r^{-2}$, where G is a universal constant (approximately 6.670×10^{-8} dyne $\text{cm}^2 \text{g}^{-2}$) called the gravitational constant.

C. Kinetic and Potential Energies

If the force \mathbf{F} on a particle is a function of the position \mathbf{x} of the particle and is the gradient $-\nabla U$ of a time-independent (scalar) function $U(\mathbf{x})$, called the **potential**, then

$$E = \frac{1}{2}mv^2 + U(\mathbf{x}) \quad \left(\mathbf{v} = \frac{d\mathbf{x}}{dt} \right)$$

is a constant of the motion of the particle.

E is called the **total energy**, while the first and second terms on the right-hand side are called the **kinetic energy** and **potential energy**, respectively.

For a system of n particles at points $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(n)}$ with masses m_1, \dots, m_n , suppose that the force acting on the particle at $\mathbf{x}^{(j)}$ is $-\nabla^{(j)}U$ (the gradient of U relative to $\mathbf{x}^{(j)}$) for a common potential function $U(\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(n)})$. Then

$$E = \sum_{j=1}^n \frac{1}{2}m_j v_j^2 + U(\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(n)}) \quad \left(\mathbf{v}_j = \frac{d\mathbf{x}^{(j)}}{dt} \right)$$

is the constant total energy of the motion. For example, Newton's gravitational force acting among a number of particles can be described by the **Newtonian potential**

$$U = \sum_{i < j} -Gm_i m_j |\mathbf{x}^{(i)} - \mathbf{x}^{(j)}|^{-1}.$$

A potential U which is a sum of functions depending only on a pair of coordinates as in the above example is called a **two-body interaction**.

D. Apparent Force

The coordinate system in which Newton's three laws of motion hold is called an **inertial system**. In some cases (e.g., on a rotating sphere such as the earth) it is more convenient to use a moving coordinate system, in which the equation of motion derived from Newton's second law by a coordinate transformation (from an inertial system to the moving coordinate system) takes a form similar to the second law except for an additional **apparent force** to be added to the force in the original equation of motion. For a coordinate system rotating at a constant angular velocity $\boldsymbol{\omega}$ (relative to an inertial system), the apparent force consists of the **centrifugal force**, of magnitude $m\omega^2\rho$ (ρ being the distance to the axis of rotation),

which pushes the particle away from the axis of rotation (along the perpendicular), and the **Coriolis force** $2m\mathbf{v} \times \boldsymbol{\omega}$ (\times denotes the vector product), which bends the motion of the particle in a direction perpendicular to both the axis of rotation and the velocity of the particle.

E. Dynamics of Rigid Bodies

A **rigid body** is defined as a system of particles whose mutual distances are permanently fixed. Like a point particle, it is an ideal concept introduced into mechanics to simplify the theoretical treatment. Actual solid bodies can in most cases be regarded as rigid under the action of forces of ordinary magnitudes. Since a rigid body can be imagined to be made up of an infinite number of particles, the equations of motion for a system of particles can also be applied to it. Thus the motion of a rigid body can be completely determined by the theorems of momentum and angular momentum.

The **momentum** of a rigid body is defined by

$$\mathbf{Q} = \int_K \frac{d\mathbf{r}}{dt} dm,$$

where dm is the mass of the volume element at a point \mathbf{r} of the rigid body K and $d\mathbf{r}/dt$ is its velocity. If the external forces acting on K are denoted by \mathbf{F}_i ($i = 1, 2, \dots$), we have

$$d\mathbf{Q}/dt = \sum \mathbf{F}_i,$$

which expresses the **theorem of momentum**.

If the velocity and acceleration of the **center of gravity** (**center of mass** or **barycenter**) $\int \mathbf{r} dm / \int dm$ of the rigid body are denoted by \mathbf{V}_G and \mathbf{A}_G , respectively, and the **mass** $\int dm$ by m , we have $\mathbf{Q} = m\mathbf{V}_G$, and the theorem of momentum becomes $m d\mathbf{V}_G/dt = m\mathbf{A}_G = \sum \mathbf{F}_i$.

The **angular momentum** of a rigid body K about an arbitrary point \mathbf{r}_0 is defined by

$$\mathbf{H} = \int_K (\mathbf{r} - \mathbf{r}_0) \times \frac{d\mathbf{r}}{dt} dm.$$

If \mathbf{P}_i is the vector from \mathbf{r}_0 to the point at which \mathbf{F}_i acts, we have

$$d\mathbf{H}/dt = \sum (\mathbf{P}_i \times \mathbf{F}_i) = \mathbf{G}.$$

This is called the **theorem of angular momentum**.

For the case of a rigid body with one point \mathbf{r}_0 fixed, the angular momentum \mathbf{H} and the angular velocity $\boldsymbol{\omega}$ are related by

$$H_x = A\omega_x - F\omega_y - E\omega_z,$$

$$H_y = -F\omega_x + B\omega_y - D\omega_z,$$

$$H_z = -E\omega_x - D\omega_y + C\omega_z,$$

where $H_x, H_y, H_z; \omega_x, \omega_y, \omega_z$ are the components of \mathbf{H} and $\boldsymbol{\omega}$ in the xyz -coordinate system

fixed in space with its origin at the fixed point \mathbf{r}_0 , and

$$A = \int (y^2 + z^2) dm, \quad B = \int (z^2 + x^2) dm,$$

$$C = \int (x^2 + y^2) dm, \quad D = \int yz dm,$$

$$E = \int zx dm, \quad F = \int xy dm,$$

with the integrals taken over the whole rigid body. We call A , B , and C the **moments of inertia** about the x -, y -, and z -axes, respectively, and D , E , F the corresponding **products of inertia**. The rotational motion of a rigid body with one axis fixed is completely determined by the theorem of angular momentum. However, for rotation about a fixed point, the theorem is not very convenient to use, because A , B , C , D , E , and F are generally unknown functions of time.

The \dagger quadric

$$Ax^2 + By^2 + Cz^2 + 2Dyz + 2Ezx + 2Fxy = 1$$

represents an ellipsoid with its center at the origin, called the **ellipsoid of inertia**. If the principal axes ξ , η , and ζ are taken as coordinate axes, the equation of the ellipsoid of inertia becomes $A\xi^2 + B\eta^2 + \Gamma\zeta^2 = 1$, where A , B , Γ are the moments of inertia about the ξ -, η -, ζ -axes and are called the **principal moments of inertia**, while the ξ -, η -, ζ -axes themselves are called the **principal axes of inertia**. If the components of the angular momentum \mathbf{H} and angular velocity in the direction of the principal axes of inertia are denoted by (H_1, H_2, H_3) and $(\omega_1, \omega_2, \omega_3)$, respectively, then $H_1 = A\omega_1$, $H_2 = B\omega_2$, $H_3 = \Gamma\omega_3$. Furthermore, if the ξ -, η -, ζ -components of the resultant moment of the external forces $\mathbf{G} = \sum(\mathbf{P}_i \times \mathbf{F}_i)$ are denoted by (G_1, G_2, G_3) , then $d\mathbf{H}/dt = \mathbf{G}$ becomes

$$A d\omega_1/dt = G_1 + (B - \Gamma)\omega_2\omega_3,$$

$$B d\omega_2/dt = G_2 + (\Gamma - A)\omega_3\omega_1,$$

$$\Gamma d\omega_3/dt = G_3 + (A - B)\omega_1\omega_2.$$

These are called **Euler's differential equations**.

The study of the motion of a rigid body can be reduced mostly to the study of the motion of its ellipsoid of inertia, since the latter is attached to the rigid body. The method of describing the motion of a rigid body by means of its ellipsoid of inertia is known as **Poinsot's representation**. The motions of two bodies having equal ellipsoids of inertia are the same if the external forces acting on them have equal resultant moments, even if their geometric forms are different.

When a rigid body moves under no constraint, the motion of its center of gravity G

can be determined by the use of the theorem of momentum. Also, the rotational motion about the center of gravity can be found from $d\mathbf{H}'/dt = \mathbf{G}'$, which is a modification of the theorem of angular momentum. Here \mathbf{H}' and \mathbf{G}' are respectively the angular momentum and moment of external forces about the center of gravity. In this case also, simplification can be achieved by considering the equation in the reference system that coincides with the principal axes of the ellipsoid of inertia with its center at the center of gravity.

F. Analytical Dynamics

Mechanics as originally formulated by Newton was geometric in nature, but later L. Euler, J. L. Lagrange, and others developed the analytical method of treating mechanics that is now called **analytical dynamics**. Lagrange introduced **generalized coordinates** q_j ($j = 1, 2, \dots, f$, where f is the number of **degrees of freedom** of the system considered), which uniquely represent the configuration of the dynamical system, and derived **Lagrange's equations of motion**:

$$\frac{d}{dt} \left(\frac{\partial \mathcal{L}}{\partial \dot{q}_j} \right) - \frac{\partial \mathcal{L}}{\partial q_j} = 0, \quad j = 1, 2, \dots, f,$$

where $\dot{q}_j = dq_j/dt$, and $\mathcal{L} = T - U$ (T = kinetic energy, U = potential energy) is a function of q_j and \dot{q}_j called the **Lagrangian function**. Later, W. R. Hamilton introduced

$$p_j = \partial T / \partial \dot{q}_j,$$

$$H = \sum p_j \dot{q}_j - \mathcal{L} = H(p_1, \dots, p_f; q_1, \dots, q_f)$$

and transformed the equations to **Hamilton's canonical equations**:

$$\frac{dq_j}{dt} = \frac{\partial H}{\partial p_j}, \quad \frac{dp_j}{dt} = -\frac{\partial H}{\partial q_j}, \quad j = 1, 2, \dots, f.$$

Here p_j is the **generalized momentum** conjugate to q_j , and q_j , p_j are called **canonical variables**.

If the functions representing the configuration of the dynamical system in terms of q_j do not explicitly contain the time t , the **Hamiltonian function** (or **Hamiltonian**) H coincides with the total energy of the system $T + U$.

The transformation $(p, q) \rightarrow (P, Q)$ under which canonical equations preserve their form is called a **canonical transformation**. It is given by

$$p_j = \frac{\partial W}{\partial q_j}, \quad P_j = -\frac{\partial W}{\partial Q_j}, \quad K = H + \frac{\partial W}{\partial t},$$

where $W = W(q_1, \dots, q_f; Q_1, \dots, Q_f)$ and K is the Hamiltonian of the transformed system. The set of canonical transformations forms a group, called a **group of canonical transforma-**

tions. An infinitesimal transformation is given by

$$dp_j = -\varepsilon \frac{\partial S}{\partial q_j}, \quad dq_j = \varepsilon \frac{\partial S}{\partial p_j},$$

where ε is an infinitesimal constant. Here S is an arbitrary function and is said to be the **generating function** of the infinitesimal transformation. Canonical equations can be interpreted to mean that the variations of p and q during the time interval $\varepsilon = dt$ are the infinitesimal canonical transformations whose generating function is $H(p, q, t)$.

The variation of an arbitrary function $F(p, q)$ under an infinitesimal transformation is given by

$$dF = \varepsilon(F, S),$$

where

$$(u, v) = \sum_j \left(\frac{\partial u}{\partial q_j} \frac{\partial v}{\partial p_j} - \frac{\partial u}{\partial p_j} \frac{\partial v}{\partial q_j} \right) = \sum_j \frac{\partial(u, v)}{\partial(q_j, p_j)}$$

is **Poisson's bracket**. Therefore the time rate of change of a dynamical quantity $F(p, q)$ can be written as

$$dF/dt = (F, H).$$

Thus the function $F(p, q)$ that satisfies $(F, H) = 0$ is an integral of the canonical equations.

If a canonical transformation $(p, q) \rightarrow (P, Q)$ such that $P_j = \alpha_j$, $Q_j = \beta_j$ are constant is found, the motion of the system can be determined by

$$p_j = \frac{\partial W}{\partial q_j}, \quad \beta_j = \frac{\partial W}{\partial \alpha_j},$$

where W is the complete solution of the **Hamilton-Jacobi differential equation**:

$$\frac{\partial W}{\partial t} + H\left(\frac{\partial W}{\partial q_1}, \dots, \frac{\partial W}{\partial q_f}; q_1, \dots, q_f, t\right) = 0$$

(\rightarrow 82 Contact Transformations).

G. Theory of Elasticity

(1) General remarks. Suppose that a solid body is deformed elastically by the action of external forces. We may inquire about the magnitudes of deformation, stress, and strain caused by the external forces at each point of the body. The **theory of elasticity** studies this problem, assuming the body to be a continuum and utilizing classical mechanics as a basis, and "endeavours to obtain results which shall be practically important in applications to architecture, engineering and all other useful arts in which the material of construction is solid" [1].

Cartesian coordinates (x, y, z) are employed for defining the 3-dimensional space contain-

ing the body. We confine ourselves to the small-displacement theory of elasticity, in which the components of the displacement $\mathbf{u} = (u, v, w)$ of an arbitrary point $P(x, y, z)$ of the body are assumed to be small enough to justify the linearization of the governing differential equations and boundary conditions.

(2) Stress. Consider an infinitesimal rectangular parallelepiped enclosed by the following six surfaces:

$$x = \text{const}, \quad y = \text{const}, \quad z = \text{const},$$

$$x + dx = \text{const}, \quad y + dy = \text{const}, \quad z + dz = \text{const},$$

in the body. The **stress** at the point $P(x, y, z)$ is defined as those internal forces per unit area acting on the six surfaces of the parallelepiped. It has nine components, which are usually represented by

$$\begin{pmatrix} \sigma_x & \tau_{yx} & \tau_{zx} \\ \tau_{xy} & \sigma_y & \tau_{zy} \\ \tau_{xz} & \tau_{yz} & \sigma_z \end{pmatrix},$$

where the σ and τ are called **normal** and **shearing** (or **tangential**) **stresses**, respectively. These nine quantities form a tensor called the **stress tensor**. Since it can be shown that $\tau_{xy} = \tau_{yx}$, $\tau_{yz} = \tau_{zy}$, $\tau_{zx} = \tau_{xz}$, the stress tensor is a symmetric tensor. By considering equilibrium conditions of the parallelepiped, the equations of equilibrium are found to be

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} + \bar{X} = 0, \dots, \dots,$$

where \bar{X}, \dots are **body forces** per unit volume.

(3) Strain. The infinitesimal rectangular parallelepiped fixed to the body at the point P before deformation is transformed, after deformation, into an infinitesimal parallelepiped which is no longer rectangular. The **strain** at the point P is defined as the changes caused by the deformation of the parallelepiped: extensions of the three sides and changes from right angles of the three angles formed by the three sides of the parallelepiped. Thus the strain has six components, usually represented by

$$(\varepsilon_x, \varepsilon_y, \varepsilon_z, \gamma_{yz}, \gamma_{zx}, \gamma_{xy}),$$

where ε and γ are called **elongation** and **shearing strains**, respectively. These six quantities, with slight modification, form a symmetric tensor called the **strain tensor**.

(4) Strain-displacement relations. In small-displacement theory, the strain-displacement relations are given in linear form by

$$\varepsilon_x = \frac{\partial u}{\partial x}, \quad \varepsilon_y = \frac{\partial v}{\partial y}, \quad \dots, \quad \gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}.$$

(5) Stress-strain relations. In the theory of elasticity, stress and strain are assumed to

obey a linear relationship called **Hooke's law**:

$$\{\sigma\} = [A] \{\varepsilon\},$$

where

$$\{\sigma\}^T = [\sigma_x, \sigma_y, \sigma_z, \tau_{yz}, \tau_{zx}, \tau_{xy}],$$

$$\{\varepsilon\}^T = [\varepsilon_x, \varepsilon_y, \varepsilon_z, \gamma_{yz}, \gamma_{zx}, \gamma_{xy}],$$

and $[A]$ is a symmetric positive definite matrix. For an isotropic body, the relations are

$$E\varepsilon_x = \sigma_x - \nu(\sigma_y + \sigma_z), \quad \dots, \quad G\gamma_{xy} = \tau_{xy},$$

where E , ν , and $G = E/2(1 + \nu)$ are elastic constants called the **modulus of elasticity in tension** or **Young's modulus**, **Poisson's ratio**, and the **modulus of elasticity in shear** or the **modulus of rigidity**, respectively.

(6) **Boundary conditions.** The surface of the body can be divided into two parts with regard to boundary conditions: the part S_1 over which the boundary conditions are prescribed in terms of external forces and the part S_2 over which the boundary conditions are prescribed in terms of displacements. Obviously $\partial V = S_1 + S_2$, where ∂V is the whole surface of the body.

(7) **Small-displacement theory of elasticity.** We have seen that the equations which govern the problem are 3 equations of equilibrium, 6 strain-displacement relations, and 6 stress-strain relations in terms of 15 unknowns, namely, 6 stress components, 6 strain components, and 3 displacement components. Thus our problem is reduced to a boundary value problem in which these 15 field equations are to be solved under the specified boundary conditions. Since all the field equations and boundary conditions are linear with respect to the unknowns under the assumption that the displacements are small, we obtain linear relationships between the external load and resulting deformation of the body; this is the **small-displacement theory of elasticity**. It should be remembered, however, that the assumption of small displacement sets limits to the application of the theory to practical problems.

(8) **Variational principles.** Several **variational principles** have been formulated in the small-displacement theory of elasticity. These include the principle of minimum potential energy $[u]$, the generalized principle $[\sigma, \varepsilon, u]$, the Hellinger-Reissner principle $[\sigma, u]$, the principle of minimum complementary energy $[\sigma]$, and so forth, where the symbols in the brackets represent independent functions subject to variation. In connection with the aforementioned variational principles, **variational principles with relaxed continuity requirements** have also been formulated by re-

laxing the continuity requirements imposed on admissible functions.

One of the practical advantages of these variational principles is that they often provide the problem with approximate formulations and approximate methods of solution, among which the **Rayleigh-Ritz method** is well known. Theories of beams, plates, shells, and multi-component structures are typical examples of such approximate formulations. Recently, these variational principles have been found to provide effective bases for the formulations of the ^{*}finite element method.

(9) **Notation.** Various symbols are used for stress and strain. For example, σ , τ and ε , γ are commonly used in the engineering literature. However, in Love's treatise [6], X_x , Y_x , Z_x and e_{xx} , e_{xy} , e_{xz} are used in place of σ_x , τ_{xy} , τ_{xz} and ε_x , γ_{xy} , γ_{xz} , respectively. Also, various notations are used for elastic constants. E is widely used, while G and ν are less common. Love uses μ and σ for G and ν , respectively. In the engineering literature the reciprocal of Poisson's ratio $m (= 1/\nu)$ is used and is called the **Poisson number**.

(10) **Finite-displacement theory of elasticity.** When the displacement of the body is no longer small (infinitesimal) but is finite, we should abandon small-displacement theory and instead employ **finite-displacement theory**, in which stress and strain are defined in a manner different from that in small-displacement theory, keeping in mind the difference between spatial and material variables. Thus equations of equilibrium, strain-displacement relations, and the boundary conditions on S_1 become nonlinear equations with stress and displacement components as unknowns, although the stress-strain relations remain linear. Thus the problem is reduced to solving a nonlinear boundary value problem, sometimes called a nonlinear elasticity problem. Variational principles have been formulated for finite-displacement theory and are frequently used in the formulation of approximate methods of solution.

When the stress becomes large enough to exceed the so-called **elastic limit**, where the linear stress-strain relationships cease to hold, the theory of elasticity is no longer valid and should be replaced by the **theory of plasticity** [9, 10].

Meromorphic Functions

A. General Remarks

A single-valued [†]analytic function in a domain D in the complex plane \mathbb{C} is called **meromorphic** in D if it has no singularities other than [†]poles. A function that is meromorphic in the whole complex plane including the point at infinity is a rational function (**Liouville's theorem**). Specifically, if a function is meromorphic in the domain \mathbb{C} , then the function is called simply a **meromorphic function**, and a meromorphic function that is not a rational function is called a **transcendental meromorphic function**. A meromorphic function $f(z)$ can be represented as a quotient of two [†]entire functions. Let $\{z_k\}$ ($k = 1, 2, \dots$) be poles of $f(z)$, and let $f_k(z) = a_{n_k}^{(k)}/(z - z_k)^{n_k} + \dots + a_1^{(k)}/(z - z_k)$ denote the [†]singular parts of $f(z)$ at z_k ($k = 1, 2, \dots$). Then $f(z)$ can also be written in the form

$$f(z) = g(z) + \sum_{k=1}^{\infty} (f_k(z) - p_k(z)),$$

where $g(z)$ is an entire function and the $p_k(z)$ ($k = 1, 2, \dots$) are rational entire functions (**Weierstrass's theorem**). Assume that a sequence $\{z_k\}$ ($k = 1, 2, \dots$) converges only to the point at infinity and that $f_k(1/(z - z_k))$ ($k = 1, 2, \dots$) are rational entire functions of $1/(z - z_k)$ which have no constant terms. Then

there exists a meromorphic function of z with $f_k(1/(z - z_k))$ as its [†]singular part at z_k (**Mittag-Leffler's theorem**).

B. Nevanlinna Theory

The theory of meromorphic functions can be considered an extension of the theory of entire functions. In particular, value distribution theory, originating in Picard's theorem, was studied by many people, and in 1925 R. Nevanlinna published a systematic theory unifying the results obtained until then. This is called **Nevanlinna theory**.

We let $f(z)$ denote a meromorphic function in $|z| < R \leq +\infty$, and when we say that $f(z)$ takes on a value, the value may be ∞ . For a value α , $n(r, \alpha)$ denotes the number of **α -points** of $f(z)$, i.e., points z with $f(z) = \alpha$, in $|z| \leq r < R$, where each α -point is counted with its multiplicity. We set

$$N(r, \alpha) = \int_0^r \frac{n(t, \alpha) - n(0, \alpha)}{t} dt + n(0, \alpha) \log r,$$

$$m(r, \alpha) = \frac{1}{2\pi} \int_0^{2\pi} \log^+ \left| \frac{1}{f(re^{i\theta}) - \alpha} \right| d\theta$$

if $\alpha \neq \infty$, and

$$N(r, \infty) = \int_0^r \frac{n(t, \infty) - n(0, \infty)}{t} dt + n(0, \infty) \log r,$$

$$m(r, \infty) = \frac{1}{2\pi} \int_0^{2\pi} \log^+ |f(re^{i\theta})| d\theta$$

if $\alpha = \infty$, where $\log^+ a = \max(\log a, 0)$ for $a > 0$.

The functions N and m are called the **counting function** and **proximity function** of $f(z)$, respectively, and $T(r) = T(r, f) = m(r, \infty) + N(r, \infty)$ is the **order function** (or **characteristic function**) of $f(z)$. $T(r)$ is an increasing function of r and a [†]convex function of $\log r$ and is useful for expressing $f(z)$ as an infinite product, etc.

The following relation holds among $T(r)$, $m(r, \alpha)$, and $N(r, \alpha)$ for any α :

$$T(r) = m(r, \alpha) + N(r, \alpha) + O(1), \quad (1)$$

where $O(1)$ is [†]Landau's symbol (**Nevanlinna's first fundamental theorem**). By this theorem, if a bounded remainder is disregarded, then $m(r, \alpha) + N(r, \alpha)$ is equal to $T(r)$ for all α . This equality thus demonstrates a beautifully balanced distribution of α -points.

We see that $N(r, \alpha)$ is in a sense the mean value of the number of α -points in $|z| \leq r$, and $m(r, \alpha)$ is the mean proximity to α of the value $f(z)$ on $|z| = r$. If the term \log^+ in the definition of the proximity function is replaced by the logarithm of the reciprocal of the chordal distance between $f(re^{i\theta})$ and α on the complex sphere, then the remainder term in (1) is

eliminated. Hence the definition of the proximity function is sometimes given in this form.

C. The Order of Meromorphic Functions

For an entire function $f(z)$, the equality

$$\limsup_{r \rightarrow \infty} \frac{\log T(r)}{\log r} = \limsup_{r \rightarrow \infty} \frac{\log \log M(r)}{\log r}$$

holds, where $M(r) = M(r, f) = \max_{|z|=r} |f(z)|$. Since the right-hand side is the order of $f(z)$ (\rightarrow 429 Transcendental Entire Functions), we define the **order (lower order)** ρ of a meromorphic function $f(z)$ by

$$\rho = \limsup_{r \rightarrow \infty} \frac{\log T(r)}{\log r} \quad \left(\liminf_{r \rightarrow \infty} \frac{\log T(r)}{\log r} \right).$$

The **order** of a meromorphic function in $|z| < R$ is also defined by

$$\rho = \limsup_{r \rightarrow R} \frac{\log T(r)}{\log(1/(R-r))}.$$

D. Meromorphic Functions on a Disk

The order function $T(r)$ is bounded if and only if $f(z)$ can be represented as the quotient of two bounded holomorphic functions $h_1(z), h_2(z)$ in $|z| < R$ (Nevanlinna). If $T(r)$ is bounded, $\lim_{r \rightarrow R} f(re^{i\theta})$ exists and is finite for every $\theta, 0 \leq \theta < 2\pi$, except possibly for a set with linear measure zero (P. Fatou and Nevanlinna). Among functions $f(z)$ such that $\lim_{r \rightarrow R} T(r) = \infty$, those satisfying

$$\limsup_{r \rightarrow R} \frac{T(r)}{\log(1/(R-r))} = \infty$$

have properties similar to those of transcendental meromorphic functions.

E. Meromorphic Functions in the Whole Finite Plane

Any meromorphic function such that

$$\limsup_{r \rightarrow R} \frac{T(r)}{\log r} < K$$

is a rational function. If $f(z)$ is a meromorphic function of order ρ and $\{r_j(\alpha)\}$, $r_j(\alpha) \leq r_{j+1}(\alpha)$ ($j = 1, 2, \dots$) is the set of absolute values of α -points, then $\sum_{j=1}^{\infty} (1/r_j(\alpha))^{\rho+\epsilon}$ converges for any α . Furthermore,

$$f(z) = z^k e^{P(z)}$$

$$\times \lim_{r \rightarrow \infty} \prod_{\substack{|a_\mu| \leq r \\ |b_\nu| \leq r}} \left(1 - \frac{z}{a_\mu} \right) \exp \left(\frac{z}{a_\mu} + \dots + \frac{z^p}{p a_\mu^p} \right) \cdot \left(1 - \frac{z}{b_\nu} \right) \exp \left(\frac{z}{b_\nu} + \dots + \frac{z^p}{p b_\nu^p} \right),$$

Meromorphic Functions

where p is the smallest integer satisfying $p+1 > \rho$, the a_μ and b_ν are the zeros and poles of $f(z)$, respectively, k is an integer, and $P(z)$ is a polynomial of degree at most p (**Hadamard's theorem**).

Let $\alpha_1, \dots, \alpha_q$ ($q \geq 3$) be distinct values. Then for any meromorphic function in $|z| < R \leq \infty$,

$$(q-2)T(r) < \sum_{j=1}^q N(r, \alpha_j) - N_1(r) + D(r),$$

$$0 \leq r < R.$$

Here

$$N_1(r) = \int_0^r \frac{n_1(t) - n_1(0)}{t} dt + n_1(0) \log r,$$

$n_1(r)$ is the number of multiple points in $|z| \leq r$ (a multiple point of order k is counted $k-1$ times), and $D(r)$ is the remainder such that if $R = \infty$, then $D(r) < K(\log T(r) + \log r)$ for some K except possibly for values of r belonging to the union of a countable number of intervals with finite total length, and if $R < \infty$, then $D(r) < K(\log T(r) + \log(1/(R-r)))$ except possibly for the union of a countable number of intervals $\{I_j\}$ with $\sum_j \int_{I_j} d(1/(R-r)) < \infty$ (**Nevanlinna's second fundamental theorem**).

Several theorems on value distribution of meromorphic functions can be obtained directly from this theorem. For instance, if $f(z)$ is a transcendental meromorphic function, the equation $f(z) = \alpha$ has an infinite number of roots for every value α except for at most two values called **Picard's exceptional values** (**Picard's theorem**). For a meromorphic function of order ρ , $\lim_{r \rightarrow \infty} \sum_{r_j \leq r} (r_j(\alpha))^{-\lambda}$ ($\lambda < \rho$) diverges for every value α except for at most two values (**Borel's theorem**). A value α for which the series converges is called a **Borel exceptional value**. We call $\delta(\alpha) = \delta(\alpha, f) = 1 - \limsup_{r \rightarrow \infty} N(r, \alpha)/T(r)$ the **defect** of f . It always satisfies $0 \leq \delta(\alpha) \leq 1$, and the values with $\delta(\alpha) > 0$ are called **Nevanlinna's exceptional values**. The number of values α (may be ∞) with $\delta(\alpha) > 0$ is at most countable for any meromorphic function $f(z)$, and $\sum_{i=1}^{\infty} \delta(\alpha_i) \leq 2$. There are many studies concerning the values α with $\delta(\alpha) = 0$.

F. Julia Directions

Among functions that have an essential singularity at the point at infinity and are meromorphic in the whole plane, there are some that possess no Julia directions. These functions, called **Julia exceptional functions**, are of order 0. A necessary and sufficient condition for $f(z)$ to be a Julia exceptional function is that $f(z)$ can be written in the form $z^m \prod_\mu (1 - z/a_\mu) / \prod_\nu (1 - z/b_\nu)$ (A. Ostrowski,

Meromorphic Functions

1925). Concerning zeros a_μ and poles b_ν of $f(z)$, the following three properties are obtained using the theory of normal families due to P. Montel: (1) There are constants K_1 , K_2 , and K_3 independent of r such that $|n(r, \infty) - n(r, 0)| < K_1$, $n(2r, \infty) - n(r, \infty) < K_2$, and $n(2r, 0) - n(r, 0) < K_3$. (2) There are constants K_4 and K_5 such that for any p and q ,

$$|a_p|^m \prod_{|a_\mu| < |a_p|} \left| \frac{a_p}{a_\mu} \right| \bigg/ \prod_{|b_\nu| < |a_p|} \left| \frac{a_p}{b_\nu} \right| < K_4,$$

$$|b_q|^{-m} \prod_{|b_\nu| < |b_q|} \left| \frac{b_q}{b_\nu} \right| \bigg/ \prod_{|a_\mu| < |b_q|} \left| \frac{b_q}{a_\mu} \right| < K_5.$$

(3) There exists an $\varepsilon > 0$ satisfying $|a_p/b_q - 1| \geq \varepsilon > 0$ for any p and q .

G. Valiron gave a precise form of Julia directions that corresponds to Borel's theorem (*Acta Math.*, 52 (1928), [3]). Namely, if the order ρ of a meromorphic function $f(z)$ in $|z| < \infty$ is positive and finite, then there exists a direction J defined by $\arg z = \alpha$ such that the zeros $z_\nu(a, \Delta)$ of $f(z) - a$ in any angular domain $\Delta: |\arg z - \alpha| < \delta$ containing J have the property $\sum_\nu |z_\nu(a, \Delta)|^{-(\rho-\varepsilon)} = \infty$ for any $\varepsilon > 0$ except for at most two values of a . The direction J is called a **Borel direction**.

G. Relations between Two or More Meromorphic Functions

Borel's unicity theorem can be stated as follows: Let f_j ($j = 1, \dots, n$) be nonvanishing entire functions satisfying $\sum_{j=1}^n f_j = 1$; then for some $(c_1, \dots, c_n) \neq (0, \dots, 0)$, $\sum_{j=1}^n c_j f_j = 0$. This is contained in the following theorem: Let f_j ($j = 1, \dots, n$) be transcendental entire functions such that $\sum_{j=1}^n f_j = 1$; then $\sum_{j=1}^n \delta(0, f_j) \leq n - 1$. If two meromorphic functions $f_1(z)$, $f_2(z)$ have the same α_j -points for five distinct values α_j ($j = 1, \dots, 5$) (where multiplicity is not taken into account), then they coincide everywhere. If the \dagger Riemann surface of the \dagger algebraic function $w(z)$ defined by a polynomial $P(z, w) = 0$ of z , w is of \dagger genus > 1 , it is impossible to find meromorphic functions $z = f(\zeta)$, $w = g(\zeta)$ that satisfy $P(f(\zeta), g(\zeta)) = 0$ (\dagger uniformization by meromorphic functions).

H. Asymptotic Values

If a meromorphic function $f(z) \rightarrow \alpha$ as $z \rightarrow \infty$ along a curve C , the value α and the curve C are called an **asymptotic value** and **asymptotic path**, respectively. Each (Picard's) exceptional value of $f(z)$ is an asymptotic value. For meromorphic functions, no simple relation is known between their order and the number of their asymptotic values. There exists a meromorphic function of order 0 with an infinite

number of asymptotic finite values. Some results analogous to those for entire functions are obtained for meromorphic functions by applying the theory of normal families. F. Marty established a systematic theory of normal families of meromorphic functions by using spherical distance.

I. Inverse Functions

Generally, the inverse function of a meromorphic function $w = f(z)$ is infinitely multiple-valued. Let $P(w, w_0)$ be a function element of the inverse function with center at w_0 , and let C be an arbitrary curve starting at w_0 and with ω its terminal point. For any domain S containing C , $P(w, w_0)$ can be continued analytically in S up to a point arbitrarily near ω (**Iversen's theorem**). Continue the function element analytically along each half-line starting at its center. Then the set of arguments of half-lines along which the analytic continuation meets a singularity at a finite point is of zero linear measure (**Gross's theorem**).

By considering the inverse image of the suitably cut Riemann surface of the inverse function, the z -plane can be divided into fundamental domains such that each domain is the inverse image of the whole w -plane (with suitable slits removed) and has a boundary each point of which is \dagger accessible from the inside of the domain, and the boundary curves of fundamental domains cluster nowhere in the plane.

For a meromorphic function $f(z)$, the set of functions $z' = \varphi(z)$ defined by $f(z') = f(z)$ (i.e., transformations between points that give $f(z)$ the same value) has the property of a \dagger hypergroup. If $\varphi(z)$ is single-valued, then it is a linear entire function, and if it is finitely multiple-valued, then it is an algebraic function. The \dagger cluster set of the inverse function at a transcendental singularity consists of only one point, ∞ , that is, it is an \dagger ordinary singularity. To an analytic continuation along a curve that determines a transcendental singularity of the inverse function there corresponds a curve in the z -plane terminating at ∞ . This curve is an asymptotic path of $f(z)$. Namely, the value $f(z)$ tends to the coordinate of the transcendental singularity as $z \rightarrow \infty$ along this path. Each asymptotic value of a transcendental meromorphic function $w = f(z)$ corresponds to a transcendental singularity of its inverse function $z = \varphi(w)$, and if we consider two asymptotic paths to be the same if they correspond to the same singularity, then there exists a one-to-one correspondence between the set of asymptotic paths and the set of transcendental singularities of the inverse

function. The inverse function of any meromorphic function of order ρ has at most 2ρ [†]direct transcendental singularities if $\rho \geq 1/2$ and at most 1 such singularity if $\rho < 1/2$ (L. V. Ahlfors).

J. Theory of Covering Surfaces

Ahlfors established the theory of covering surfaces by a metricotopological method and in applying it, obtained Nevanlinna theory and many other results on meromorphic functions.

Let F_r denote the covering surface of the Riemann sphere F_0 with radius $1/2$; F_r is the image of $|z| \leq r$ under a meromorphic function $w = f(z)$. The area of F_r divided by π , where π is the area of F_0 , is given by

$$A(r) = \frac{1}{\pi} \iint_{|z| \leq r} \frac{|f'(z)|^2}{(1 + |f(z)|^2)^2} \rho \, d\rho \, d\theta,$$
$$z = \rho e^{i\theta},$$

and is called the **mean number of sheets** of F_r . The length of the boundary of F_r is given by

$$L(r) = \int_{|z|=r} \frac{|f'(z)|}{1 + |f(z)|^2} |dz|.$$

The relation

$$T(r) = \int \frac{A(r)}{r} dr + O(1)$$

holds (T. Shimizu, Ahlfors).

Consider the Riemann surface of the inverse function of a meromorphic function $w = f(z)$ in $|z| < R \leq +\infty$. It has a countable number of components Q_v over a domain on the w -plane. Let Δ_v denote the inverse image of Q_v on the z -plane. If Δ_v together with its boundary is contained in $|z| < R$, the component Q_v is called an **island**, and otherwise, a **peninsula**.

Let D be a simply connected domain of the w -plane, $n(r, D)$ be the sum of the sheet numbers of the islands of F_r over D , and $m(r, D)$ be the sum of the areas of the peninsulas of F_r over D divided by the area of D . Then

$$m(r, D) + n(r, D) = A(r) + O(L(r)).$$

Let D_j ($j = 1, \dots, q$) ($q \geq 3$) be disjoint simply connected domains on the w -plane. Then

$$\sum_{j=1}^q n(r, D_j) - \sum_{j=1}^q n_1(r, D_j) > (q-2)A(r) - O(L(r)),$$

where $n_1(D)$ is the sum of the orders of branch points in all islands of F_r over D .

For a meromorphic function $f(z)$, $L(r) < A(r)^{1/2+\epsilon}$, where r satisfies $0 \leq r < \infty$ except for $r \in \bigcup_j I_j$ for some intervals I_j . Hence in the case where D_j is a point α_j , this inequality

yields

$$\sum_{j=1}^q n(r, \alpha_j) - \sum_{j=1}^q n_1(r, \alpha_j) > (q-2)A(r) - O(A(r)^{1/2+\epsilon})$$

with some exceptional intervals of values of r . This latter important inequality corresponds to Nevanlinna's second fundamental theorem. Let D_j ($j = 1, \dots, q$) ($q \geq 3$) be disjoint simply connected domains on the w -plane. If every simply connected island over D_j has at least μ_j sheets, then $\sum_{j=1}^q (1 - (1/\mu_j)) \leq 2$ (**disk theorem**). It follows from this theorem that given three disjoint disks D_j on the Riemann sphere, there is at least one D_j that has an infinite number of islands over it, and also that given five D_j , there exists at least one D_j that has a 1-sheeted island over it (**Ahlfors's five-disk theorem**). This theorem corresponds to [†]Bloch's theorem for entire functions. These theorems can also be obtained for meromorphic functions on a disk. Ahlfors established a more important theory by introducing a differential metric.

K. Recent Development

The Nevanlinna brothers raised several important problems, which gave strong motivation for later investigations. The first major breakthrough after World War II was given by A. Gol'dberg in 1956. He gave an example which has infinitely many deficient values (Nevanlinna's exceptional values). W. Hayman proved that $\sum \delta(a, f)^{\alpha}$ converges for $\alpha > 1/3$, and there are examples of meromorphic functions for which the series diverges for $\alpha < 1/3$. Finally, A. Weitsman showed that the series converges for $\alpha = 1/3$. The second major breakthrough was given by A. Edrei and W. Fuchs in 1959, whose works concern the following Nevanlinna theorem: Let $K(f)$ be

$$\limsup_{r \rightarrow \infty} \frac{N(r, 0) + N(r, \infty)}{T(r, f)}$$

and $\kappa(\rho) = \inf K(f)$, where \inf is taken over all meromorphic function f of order ρ . Then $\kappa(\rho) > 0$ if ρ is neither a positive integer nor ∞ . Furthermore, Nevanlinna gave a conjecture for an exact value of $\kappa(\rho)$. This conjecture is still open, although several estimates have appeared. In the case of entire functions having only negative zeros the conjecture was positively solved by S. Hellerstein and J. Williamson. Edrei and Fuchs proved that $\kappa(\rho) = 1$ for $0 \leq \rho \leq 1/2$ and $\kappa(\rho) = \sin \pi \rho$ for $1/2 < \rho \leq 1$. They also proved the ellipse theorem: Let $f(z)$ be a transcendental meromorphic function of order ρ ($0 \leq \rho \leq 1$). Put $u = 1 - \delta(a, f)$, $v = 1 - \delta(b, f)$. Then $u, v \in [0, 1]$ and $u^2 - 2uv \cos \pi \rho + v^2 \geq \sin^2 \pi \rho$. If further $u < \cos \pi \rho$, then $v = 1$.

For the sum of deficiencies Edrei proved that

$$\sum \delta(a, f) \leq \begin{cases} 1 - \cos \pi \rho & (0 \leq \rho \leq 1/2) \\ 2 - \sin \pi \rho & (1/2 < \rho \leq 1) \end{cases}$$

unless the number of deficient values is one. It was conjectured that $\sum \delta(a, f) = 2$ implies that the order ρ of f is a half integer, the number v of deficient values is at most 2ρ , and the value of $\delta(a, f)$ is a multiple of $1/\rho$. For the case of entire functions this conjecture is true (A. Pfluger). Weitsman proved that $v \leq 2\rho$. Other cases remain open. All the above results still hold even if the order is replaced by the lower order. The inverse problem was completely solved by D. Drasin. Many of the above results depend on the concept of Pólya peaks.

N. V. Govorov and V. Petrenko proved independently that

$$\liminf_{r \rightarrow \infty} \frac{\log M(r, f)}{T(r, f)} \leq \pi \rho \quad \text{for } \rho > 1/2$$

for every entire function of order ρ . This was a conjecture made by R. Paley. For $\rho \leq 1/2$, an exact upper bound $\pi \rho / \sin \pi \rho$ was given by Valiron. Furthermore, the following result was proved by Edrei and Fuchs:

$$\limsup_{r \rightarrow \infty} \frac{N(r, 0)}{\log M(r, f)} \geq \frac{\sin \pi \rho}{\pi \rho} \quad (0 \leq \rho < 1).$$

L. History

The value distribution theory of meromorphic functions had its inception with the classical Picard theorem. It first appeared as the value distribution theory of entire functions and was developed into a well-organized field by way of the Nevanlinna theory and the Ahlfors theory of covering surfaces. In recent years, emphasis has also been placed on the study of meromorphic functions on open Riemann surfaces (\rightarrow 367 Riemann Surfaces). The value distribution of a set of several meromorphic functions was studied first by A. Bloch and developed into the study of **meromorphic curves** by Ahlfors, and H. and J. Weyl [2]. The behavior of meromorphic functions in neighborhoods of general singularities has also been studied. An example of results in that field is the theory of \dagger cluster sets.

273 (II.17) Metric Spaces

A. General Remarks

The distance between two points $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ in the n -dimensional \dagger Euclidean space \mathbf{R}^n is defined by $\rho(x, y) = \sqrt{(y_1 - x_1)^2 + \dots + (y_n - x_n)^2}$. The function $\rho(x, y)$ is nonnegative for every pair (x, y) and has the following properties: (i) $\rho(x, y) = 0$ if and only if $x = y$; (ii) $\rho(x, y) = \rho(y, x)$; and (iii) $\rho(x, z) \leq \rho(x, y) + \rho(y, z)$ for any three points x, y, z . Property (iii) is called the **triangle inequality**.

B. Definition of Metric Spaces

Abstracting the notion of distance from Euclidean spaces, M. Fréchet defined metric

spaces [1] (1906). A **metric** on a set X is a nonnegative function ρ on $X \times X$ that satisfies (i), (ii), and (iii) of Section A, and a **metric space** (X, ρ) , or simply X , is a set X provided with a metric ρ . The members of X are called points, ρ is called the **distance function**, and $\rho(x, y)$ is called the **distance** from x to y . The distance function is sometimes denoted by $d(x, y)$ or $\text{dis}(x, y)$. If (i) is replaced by its weaker form (i') $\rho(x, x) = 0$, the function ρ is called a **pseudometric** (or **pseudodistance function**), and X is called a **pseudometric space**.

Examples of metric spaces:

(1) The n -dimensional Euclidean space \mathbf{R}^n , in particular the real number system \mathbf{R} with $\rho_0(x, y) = |x - y|$. (2) The \dagger function space $L_p(\Omega)$. (3) The \dagger function space $C(\Omega)$. (4) The \dagger sequence space s , i.e., the space $\mathbf{R}^{\mathbb{N}}$ of all sequences of real numbers with metric $\rho(x, y) = \sum_{n=1}^{\infty} 2^{-n} |x_n - y_n| / (1 + |x_n - y_n|)$, where $x = (x_1, x_2, \dots)$ and $y = (y_1, y_2, \dots)$. (5) The \dagger sequence space m , i.e., the space of all bounded sequences of real numbers with metric $\rho(x, y) = \sup_n |x_n - y_n|$ for $x = (x_1, x_2, \dots)$ and $y = (y_1, y_2, \dots)$. (6) A **Baire zero-dimensional space** $(\Omega^{\mathbb{N}}, \rho)$, where Ω is a set and the distance $\rho(x, y)$ between $x = (x_1, x_2, \dots)$ and $y = (y_1, y_2, \dots)$ is equal to the reciprocal of the minimum n such that $x_n \neq y_n$. When the cardinal number τ of Ω is specified, the Baire space is denoted by $B(\tau)$. (7) For any set X , define ρ by setting $\rho(x, x) = 0$ and $\rho(x, y) = 1$ when $x \neq y$. Then (X, ρ) is a metric space, called a **discrete metric space**. (8) For any set X , define ρ by setting $\rho(x, y) = 0$ for any members x and y . Then ρ is a pseudometric, and the resulting space X is called an **indiscrete pseudometric space**.

For a subset M of a metric space X , $\sup\{\rho(x, y) \mid x, y \in M\}$ is called the **diameter** of M (denoted by $d(M)$), and M is said to be **bounded** if its diameter is finite (including $M = \emptyset$). For two subsets A, B of X , $\inf\{\rho(x, y) \mid x \in A, y \in B\}$ is called the **distance** between A and B , denoted by $\rho(A, B)$. We have $\rho(A, B) = \rho(B, A)$. When a family $\mathfrak{M} = \{M_\lambda \mid \lambda \in \Lambda\}$ of subsets of X is a covering of X , i.e., $X = \bigcup_\lambda M_\lambda$, the supremum of the diameters $d(M_\lambda)$ of M_λ in \mathfrak{M} , $\sup\{d(M_\lambda) \mid \lambda \in \Lambda\}$, called the **mesh of the covering** \mathfrak{M} . For a positive number ε , a covering whose mesh is less than ε is called an ε -**covering**. A metric space X is called **totally bounded** (or **precompact**) (F. Hausdorff, 1927) if for each positive number ε there exists a finite ε -covering of X .

A subset X_1 of a metric space X becomes a metric space if we define its metric ρ_1 by setting $\rho_1(x, y) = \rho(x, y)$ for $x, y \in X_1$, where ρ is the metric of X . The space (X_1, ρ_1) is called a **metric subspace** of (X, ρ) . A subset of X is called **totally bounded** (or **precompact**) if it is

totally bounded as a metric subspace. Any totally bounded subset is bounded. Conversely, in the Euclidean space \mathbf{R}^n any bounded subset is totally bounded.

A bijection f from a metric space (X_1, ρ_1) onto a metric space (X_2, ρ_2) is called an **isometric mapping** if f preserves the metric, i.e., $\rho_2(f(x), f(y)) = \rho_1(x, y)$ for any points $x, y \in X_1$; and X_1 and X_2 are called **isometric** if there is an isometric mapping from X_1 onto X_2 .

Let X be a metric space with metric ρ , and let f be an injection from a set Y into X . Then the function $\rho'(y_1, y_2) = \rho(f(y_1), f(y_2))$ ($y_1, y_2 \in Y$) is a distance function on Y , and with this metric the set Y becomes a metric space called the **metric space induced by f** ; f is an isometric mapping from (Y, ρ') onto $(f(Y), \rho)$.

For a finite number of metric spaces $(X_1, \rho_1), \dots, (X_n, \rho_n)$, we can define a metric ρ on their Cartesian product $X = X_1 \times \dots \times X_n$ by setting

$$\rho(x, y) = \sqrt{\rho_1(x_1, y_1)^2 + \dots + \rho_n(x_n, y_n)^2},$$

for two points $x = (x_1, \dots, x_n), y = (y_1, \dots, y_n)$ of X . Thus we obtain a metric space (X, ρ) , called the **product metric space** of $(X_1, \rho_1), \dots, (X_n, \rho_n)$. The n -dimensional Euclidean space \mathbf{R}^n is the product metric space of n copies of the real line (\mathbf{R}, ρ_0) .

C. Topology for Metric Spaces

For a point x of a metric space (X, ρ) and any positive number ε , the set $U_\varepsilon(x)$ of all points y such that $\rho(x, y) < \varepsilon$ is called the ε -**neighborhood** (or ε -**sphere**) of x . We can introduce a topology for X by taking the family of all ε -neighborhoods as a \dagger base for the neighborhood system (\rightarrow 425 Topological Spaces). Then the following five propositions hold, any one of which can be used to define the same topology: (i) A subset O is \dagger open if and only if for any point x in O there is a positive number ε such that the ε -neighborhood of x is contained in O . (ii) A subset F is \dagger closed if and only if any point whose every ε -neighborhood contains at least one point of F is contained in F . (iii) A subset U is a neighborhood of a point x if and only if U contains some ε -neighborhood of x . (iv) A point x is an \dagger interior point of a subset A if and only if some ε -neighborhood of x is contained in A ; the interior A^i of A is the set of all such points. (v) A point x is adherent to a subset A if every ε -neighborhood of x contains at least one point of A ; the closure \bar{A} of A is the set of all such points, and $x \in \bar{A}$ if and only if $\rho(x, A) = 0$.

Every metric space X satisfies the \dagger first countability axiom. A metric space X is a

*Hausdorff space and, more specifically, a *perfectly normal space; it is also *paracompact.

In the same way, we can define a topology for each pseudometric space that satisfies the first countability axiom, but a pseudometric space is not necessarily Hausdorff.

D. Convergence of Sequences

A sequence $\{x_n\}$ of points in a metric space is said to **converge** to a point x (written $\lim_{n \rightarrow \infty} x_n = x$) if $\rho(x_n, x)$ tends to zero as $n \rightarrow \infty$. The point x is called the **limit** of $\{x_n\}$. This convergence is equivalent to convergence with respect to the topology defined in Section C (\rightarrow 87 Convergence). As the first countability axiom is satisfied, we may define the topology by means of convergent sequences of points: the closure \bar{A} of a subset A is the set of all limits of sequences of points in A .

E. Separable Metric Spaces

For a metric space X the following three conditions are equivalent: (i) There exists a countable family \mathfrak{D}_0 of open sets of X such that each open set of X is the union of members of \mathfrak{D}_0 (*second countability axiom). (ii) X is *separable, that is, X has a countable subset that is *dense in X . (iii) Every open covering of X has a countable subcovering (*Lindelöf space). A metric space with any of these properties is called a **separable metric space**. The sequence space s is separable. Any separable metric space can be isometrically embedded in the sequence space m , i.e., is isometric to a subspace of m (\rightarrow 168 Function Spaces B).

F. Compact Metric Spaces

For a metric space X , the following five conditions are equivalent: (i) X is *compact, that is, every open covering of X has a finite subcovering. (ii) X is *countably compact, that is, every countable open covering of X has a finite subcovering. (iii) X is *sequentially compact, that is, any sequence of points in X has a convergent subsequence. (iv) Every nested family $F_1 \supset F_2 \supset \dots$ of nonempty closed sets of X has a nonempty intersection. (v) Every infinite subset M of X has an accumulation point x , i.e., $x \in \overline{M - \{x\}}$. A metric space satisfying any of these conditions is called a **compact metric space** (M. Fréchet [1]). Every real-valued continuous function defined on a compact metric space has a maximum and a minimum. A metric space is compact if and only if it is totally bounded and complete (\rightarrow Section J). Every totally bounded metric space is

separable. In particular, every compact metric space is separable.

Let $\mathfrak{U} = \{U_\lambda\}$ be an open covering of a compact metric space X . There exists a positive number δ such that every set with $d(A) < \delta$ is contained in some U_λ . The number δ is called the **Lebesgue number** of the open covering \mathfrak{U} .

A subset A of a metric space is said to be **compact** if it is compact as a metric subspace, and A is said to be **relatively compact** if its closure is compact. Bounded closed sets in \mathbf{R}^n , in particular closed intervals of real numbers, are compact. For these sets, conditions (i), (iv), and (v) are called the **Heine-Borel theorem** (or **Borel-Lebesgue theorem**), **Cantor's intersection theorem**, and the **Bolzano-Weierstrass theorem**, respectively.

G. Product Spaces of Metric Spaces

Let $(X_1, \rho_1), \dots, (X_n, \rho_n)$ be metric spaces. Then the Cartesian product $X = X_1 \times \dots \times X_n$ has distance functions

$$\bar{\rho}_p(x, y) = \{\rho_1(x_1, y_1)^p + \dots + \rho_n(x_n, y_n)^p\}^{1/p},$$

$p \geq 1$

and

$$\bar{\rho}_\infty(x, y) = \max\{\rho_1(x_1, y_1), \dots, \rho_n(x_n, y_n)\},$$

where $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$. The topology of X induced by each one of these metrics coincides with the product topology. In particular, for the n -dimensional Euclidean space \mathbf{R}^n , the metrics $\bar{\rho}_p$ ($p \geq 1$) and $\bar{\rho}_\infty$ define the same topology.

Let $(X_1, \rho_1), \dots, (X_n, \rho_n), \dots$ be a countable number of metric spaces. If we define a metric ρ on the Cartesian product $X = \prod_{n=1}^\infty X_n$ by

$$\rho(x, y) = \sum_{n=1}^\infty \frac{1}{2^n} \frac{\rho_n(x_n, y_n)}{1 + \rho_n(x_n, y_n)},$$

where $x = (x_1, x_2, \dots)$ and $y = (y_1, y_2, \dots)$, then the topology defined by ρ is identical with the product topology. For the Cartesian product of an uncountable number of metric spaces, we cannot construct a metric ρ such that the topology induced by ρ agrees with the product topology in general.

H. Uniformity of Metric Spaces

Every metric space X is a *uniform space, for which we may take a countable number of subsets $\{(x, y) | \rho(x, y) < 2^{-n}\}$, $n = 1, 2, \dots$, of $X \times X$ as a base of *uniformity (\rightarrow 436 Uniform Spaces).

I. Uniform Continuity

A mapping f from a metric space (X, ρ) into a metric space (Y, σ) is \dagger continuous if for any point x in X and any positive number ε there is a positive number δ such that $f(U_\delta(x)) \subset V_\varepsilon(f(x))$, where $U_\delta(x)$ is a δ -neighborhood for ρ and $V_\varepsilon(y)$ is an ε -neighborhood for σ ; that is, $\rho(x, x') < \delta$ implies $\sigma(f(x), f(x')) < \varepsilon$. In this case, we must generally choose δ depending on x and ε . In the special case where we can choose δ depending only on ε , independently of x , we call f **uniformly continuous** in X . (The notion of uniform continuity may be generalized to uniform spaces.) Not every continuous mapping is necessarily uniformly continuous, but every continuous mapping from a compact metric space into a metric space is uniformly continuous.

J. Complete Metric Spaces

A sequence $\{x_n\}$ of points in a metric space (X, ρ) is called a **fundamental sequence** (or **Cauchy sequence**) if $\rho(x_n, x_m) \rightarrow 0$ as $n, m \rightarrow \infty$. Every convergent sequence is a fundamental sequence, but the converse is not always true. A metric space is called **complete** if every fundamental sequence in the space converges to some point of the space (M. Fréchet [1]). A topological space that is homeomorphic with a complete separable metric space is sometimes called a **Polish space** (\rightarrow 22 Analytic Sets I). The metric spaces introduced in examples (1) through (5) of Section B are complete. (In example (3) we must assume that the space Ω is a compact Hausdorff space.) A metric space is compact if and only if it is complete and totally bounded. A \dagger locally compact metric space is homeomorphic to a complete metric space.

For a metric space X , we can construct a complete metric space Y such that there is an isometric mapping φ from X onto a dense subspace X_1 of Y (F. Hausdorff, 1914). Such a pair (Y, φ) is called a **completion** of X . If X has two completions (Y_1, φ_1) and (Y_2, φ_2) , then there is an isometric mapping f from Y_1 onto Y_2 with $\varphi_2 = f \circ \varphi_1$. In this sense the completion of X is unique. By identifying X with $\varphi(X)$ when (Y, φ) is the completion of X , any metric space can be regarded as a dense subspace of a complete metric space. For example, the completion of the rational number system \mathbf{Q} is the real number system \mathbf{R} . A metric space is totally bounded ($=$ precompact) if and only if its completion is compact.

Baire-Hausdorff theorem: In a complete metric space every set of the \dagger first category is a \dagger boundary set. That is, every set that can be

expressed as the union of a countable number of sets whose closures have no interior point has no interior point. In other words, if the union $\bigcup_{n=1}^{\infty} F_n$ of closed sets F_1, F_2, \dots of X has an interior point, then at least one of the F_n must have an interior point.

K. The Metrization Problem

A topological space X is called **metrizable** if we can introduce a suitable metric for X which induces a topology identical to the original one. A $\dagger T_1$ -space satisfying the second countability axiom is metrizable if and only if it is \dagger regular (**Uryson-Tikhonov theorem**; P. S. Uryson, *Math. Ann.*, 94 (1925), A. Tikhonov, *Math. Ann.*, 95 (1925)). However, a metric space does not necessarily satisfy the second countability axiom. Therefore, the Uryson-Tikhonov theorem does not provide a necessary and sufficient condition for metrizability. The following are some necessary and sufficient conditions for a topological space X to be metrizable:

(1) There exists a nonnegative real-valued function d on $X \times X$ satisfying the first two axioms given in Section A and the following condition: There exists a real-valued function $\varphi(w)$ that converges to zero as $w \rightarrow 0$ such that, for any three points x, y, z and any positive number ε , $d(x, y) < \varphi(\varepsilon)$ and $d(y, z) < \varphi(\varepsilon)$ imply $d(x, z) < \varepsilon$ (E. W. Chittenden, *Trans. Amer. Math. Soc.*, 18 (1917)).

(2) X is a T_1 -space that has a countable number of open coverings $\mathfrak{M}_1, \mathfrak{M}_2, \dots$ satisfying the following two conditions: (i) If $U_1, U_2 \in \mathfrak{M}_{n+1}$ have a common point, there is a set $U \in \mathfrak{M}_n$ with $U \supset U_1 \cup U_2$; (ii) for any point x in X , if U_n is any member of \mathfrak{M}_n containing x , the family $\{U_n\}_{n=1,2,\dots}$ is a base for the neighborhood system of x (P. S. Aleksandrov and Uryson, *C. R. Acad. Sci., Paris*, 177 (1923), and N. Aronszajn). When X is a uniform space, this amounts to saying that X has a metric compatible with the uniform structure if and only if X is a T_1 -space and has a countable base of uniformity.

(3) X is a T_1 -space that admits a countable number of open coverings $\mathfrak{M}_1, \mathfrak{M}_2, \dots$ such that $\{S(S(x, \mathfrak{M}_i), \mathfrak{M}_j) | i, j = 1, 2, \dots\}$ is a base for the neighborhood system of x at each point of X , where $S(A, \mathfrak{M})$ is the \dagger star of A relative to \mathfrak{M} (R. L. Moore, *Fund. Math.*, 25 (1935); K. Morita, *Proc. Japan Acad.*, 27 (1951); A. H. Stone, *Pacific J. Math.*, 10 (1960); A. V. Arkhangel'skii, *Dokl. Akad. Nauk SSSR*, 2 (1961)).

(4) X is regular and has a $\dagger \sigma$ -locally finite open base (J. Nagata, *J. Inst. Polytech. Osaka City Univ.*, 1 (1950); Yu. M. Smirnov, *Uspekhi Mat. Nauk*, 6 (1951)).

(5) X is regular and has a $\dagger\sigma$ -discrete open base (R. H. Bing, *Canad. J. Math.*, 3 (1951)).

(6) X is a \dagger collectionwise normal Moore space (\rightarrow below; Bing, *ibid.*).

(7) X is a \dagger perfect image of a subspace of a Baire's zero-dimensional space (Morita, *Sci. Rep. Tokyo Kyoiku Daigaku*, sec. A, 5 (1955)).

(8) X is a Hausdorff $\dagger M$ -space such that the diagonal is a $\dagger G_\delta$ -set in the direct product $X \times X$ (A. Okuyama, *Proc. Japan Acad.* 40 (1964); C. J. R. Borges, *Pacific J. Math.*, 17 (1966); J. Chaber, *Fund. Math.*, 94 (1977)).

A regular space is said to be a Moore space if it has a countable number of open coverings \mathfrak{M}_i such that $\{S(x, \mathfrak{M}_i)\}$ is a base for the neighborhood system of x for any point x . A Moore space is not necessarily metrizable. F. B. Jones (*Bull. Amer. Math. Soc.*, 43 (1937)) proved under the assumption $2^{\aleph_0} < 2^{\aleph_1}$ that every separable normal Moore space is metrizable and asked whether or not every normal Moore space is metrizable. (3) and (6) are partial answers to the question. A normal Moore space is metrizable if it is locally compact and \dagger locally connected (G. Reed and P. Zenor). The existence of a nonmetrizable separable normal Moore space is consistent with and independent of the axioms of the usual ZFC set theory, the \dagger Zermelo-Fraenkel set theory with the \dagger axiom of choice (F. D. Tall). W. G. Fleissner (*Trans. Amer. Math. Soc.*, 273 (1982)) constructed a normal nonmetrizable Moore space assuming an axiom weaker than the continuum hypothesis, while P. J. Nyikos (1980) has proved that every normal space with the first countability axiom is collectionwise normal from the strong axiom of set theory.

In connection with (7) the following result is known. Let f be a \dagger closed continuous mapping from a metric space X onto a topological space Y . Then the following conditions are equivalent: (1) Y is metrizable; (2) For each $y \in Y$ the \dagger boundary $\partial f^{-1}(y)$ of the inverse image is compact; (3) Y satisfies the first countability axiom (Morita and S. Hanai, *Proc. Japan Acad.*, 32 (1956); Stone, *Proc. Amer. Math. Soc.*, 7 (1956); I. A. Vainstein, *Dokl. Akad. Nauk SSSR*, 57 (1947)). In particular, perfect images of metric spaces are metrizable.

274 (XII.16) Microlocal Analysis

A. General Remarks

Let X be an open set of \mathbf{R}^n . Then $X \times (\mathbf{R}^n \setminus 0)$ can be identified with $T^*X \setminus 0$, the \dagger cotangent bundle of X minus the zero-section. To every locally integrable function (or distribution or hyperfunction (\rightarrow 125 Distributions and Hyperfunctions)) $f(x)$ defined on X , one can assign closed subsets of $X \times (\mathbf{R}^n \setminus 0)$ called the wave front set of f and the singularity spectrum (or analytic wave front set or essential support) of f . The wave front set (resp. the singularity spectrum) of f describes in detail the singularity of f modulo the infinitely differentiable functions (resp. the real analytic functions). One can further associate with f more refined objects defined on $X \times (\mathbf{R}^n \setminus 0)$, such as microfunctions. In many cases one can recover knowledge of the structure of f by analyzing these objects defined on $X \times (\mathbf{R}^n \setminus 0)$. Such an analysis on the cotangent bundle of X is called **microlocal analysis**. Microlocal analysis is particularly successful if f is a solution of a system of linear (pseudo-)differential equations, because in that case one can use various linear transformations, such as differential operators, pseudodifferential operators (\rightarrow 345 Pseudodifferential Operators), or microdifferential operators and Fourier integral operators, or quantized contact transformations.

B. Microlocal Analysis for Distributions

Let u be a distribution defined in an open subset X of \mathbf{R}^n . The **wave front set** $\text{WF}(u)$ of u is defined as the complement in $X \times (\mathbf{R}^n \setminus 0)$ of the collection of all (x_0, ξ_0) in $X \times (\mathbf{R}^n \setminus 0)$ such that for some neighborhood U of x_0 , V of ξ_0 we have for each $\varphi \in C_0^\infty(U)$ and each $N > 0$,

$$\langle u, \varphi \exp(-i\tau x \cdot \xi) \rangle = O(\tau^{-N})$$

as $\tau \rightarrow \infty$, uniformly in $\xi \in V$ (L. Hörmander; [1]). $\text{WF}(u)$ is considered to be a subset of

$T^*X \setminus \{0\}$. If $\text{WF}(u) = \emptyset$, then u is a C^∞ -function. Let $\pi: X \times (\mathbf{R}^n \setminus 0) \rightarrow X$ be the natural projection. If $\pi(\text{WF}(u))$ contains x_0 , then u is not a C^∞ -function in any small neighborhood of x_0 . Thus $\text{WF}(u)$ is the obstruction for u to be infinitely differentiable. Let $p(x, D)$ be a \dagger linear partial differential operator of order m . Assume that $p(x, D)u = f$. Then

$$\text{WF}(f) \subset \text{WF}(u) \subset \text{WF}(f) \cup p_m^{-1}(0),$$

where $p_m: (x, \xi) \rightarrow p_m(x, \xi)$ is the \dagger principal symbol of $p(x, D)$. Such a technique of localizing the problem on the cotangent bundle has been used in the form of the estimation of the Fourier transform of f since the advent of the \dagger singular integral operators of A. P. Calderón and A. Zygmund [3, 4] (see also S. Mizohata [5, 6]). The formula above contains as a special case the classical result that u is a C^∞ -function if $p(x, D)$ is \dagger elliptic and if f is a C^∞ -function.

In obtaining useful results of microlocal analysis for distributions one often uses Fourier integral operators and pseudodifferential operators (or singular integral operators) (→ 345 Pseudodifferential Operators).

C. Fourier Integral Operators [1, 2, 7–9]

A Fourier integral operator $B: C_0^\infty(\mathbf{R}^n) \rightarrow \mathcal{D}'(\mathbf{R}^n)$ is a locally finite sum of linear operators of the type

$$Af(x) = (2\pi)^{-(n+N)/2} \int_{\mathbf{R}^{n+N}} a(x, \theta, y) \times \exp(i\varphi(x, \theta, y)) f(y) dy d\theta.$$

Here $a(x, \theta, y)$ is a C^∞ -function satisfying the inequality

$$|D_x^\alpha D_\theta^\beta D_y^\gamma a(x, \theta, y)| \leq C(1 + |\theta|)^{m-\rho|\beta| + (1-\rho)(|\alpha| + |\gamma|)}$$

for some fixed m and ρ , $1 \geq \rho > 1/2$, and any triple of \dagger multi-indices α, β, γ , and $\varphi(x, \theta, y)$ is a real-valued C^∞ -function which is homogeneous of degree 1 in θ for $|\theta| > 1$. The function φ is called the **phase function** and a the **amplitude function**.

Let $C_\varphi = \{(x, \theta, y) | d_\theta \varphi(x, \theta, y) = 0, \theta \neq 0\}$ and $W = \{(x, y) \in \mathbf{R}^n \times \mathbf{R}^n | \exists \theta \neq 0 \text{ such that } (x, \theta, y) \in C_\varphi\}$. If $d_{x, \theta, y} \varphi(x, \theta, y) \neq 0$ for $\theta \neq 0$, then the kernel distribution $k(x, y)$ of A is of class C^∞ outside W . A phase function φ is called nondegenerate if the $d_{x, \theta, y}(\partial \varphi(x, \theta, y) / \partial \theta_j)$, $j = 1, 2, \dots, N$, are linearly independent at every point of C_φ . In this case, C_φ is a smooth manifold in \mathbf{R}^{n+N+n} and the mapping $\Phi: C_\varphi \ni (x, \theta, y) \rightarrow (x, y, \xi, \eta)$, $\xi = d_x \varphi(x, \theta, y)$, $\eta = d_y \varphi(x, \theta, y)$, is an immersion of C_φ to $T^*(\mathbf{R}^n \times \mathbf{R}^n) \setminus 0$, the cotangent bundle of $\mathbf{R}^n \times \mathbf{R}^n$ minus its zero-section. The image $\Phi C_\varphi = \Lambda_\varphi$ is a **conic Lagrangian manifold**, i.e., the canonical 2-form σ

$= \sum_j d\xi_j \wedge dx_j - \sum_j d\eta_j \wedge dy_j$ vanishes on Λ_φ and the multiplicative group of positive numbers acts on Λ_φ . Let $\lambda_1, \lambda_2, \dots, \lambda_{2n}$ be a system of local coordinates in Λ_φ . These, together with $\partial \varphi / \partial \theta_1, \partial \varphi / \partial \theta_2, \dots, \partial \varphi / \partial \theta_N$, constitute a system of local coordinate functions of \mathbf{R}^{n+N+n} in a neighborhood of C_φ . Let J denote the Jacobian determinant

$$\frac{D\left(\lambda_1, \lambda_2, \dots, \lambda_{2n}, \frac{\partial \varphi}{\partial \theta_1}, \dots, \frac{\partial \varphi}{\partial \theta_N}\right)}{D(x, \theta, y)}.$$

The function $a_{\Lambda_\varphi} = \sqrt{J} a|_{C_\varphi} \Phi^{-1} \exp(\pi Mi/4)$ is called the **symbol** of A . Here $a|_{C_\varphi}$ is the restriction of a to C_φ and M is an integer called the **Keller-Maslov index** [10, 11]. The conic Lagrangian manifold $\Lambda_\varphi = \Lambda_\varphi(A)$ and the symbol $a_{\Lambda_\varphi} = a_{\Lambda_\varphi}(A)$ essentially determine the singularity of the \dagger kernel distribution $k(x, y)$ of the Fourier integral operator A . Conversely, given a conic Lagrangian manifold Λ in $T^*(\mathbf{R}^n \times \mathbf{R}^n) \setminus 0$ and a function a_Λ on it, one can construct locally a Fourier integral operator A such that $\Lambda_\varphi(A) = \Lambda$ and $a_{\Lambda_\varphi}(A) = a_\Lambda$. For global construction of such a Fourier integral operator one requires detailed consideration of the Keller-Maslov index. A globally defined Fourier integral operator A with $\Lambda_\varphi(A) = \Lambda$ and $a_{\Lambda_\varphi}(A) = a_\Lambda$ exists if and only if a_Λ is not a function on Λ but a section of the complex line bundle $\Omega_{1/2} \otimes L$, where $\Omega_{1/2}$ is the bundle of square roots of the volume elements of Λ and L is a \mathbf{Z}_4 bundle over Λ called the **Maslov bundle**. The factor $\sqrt{J} \exp(\pi Mi/4)$ in the definition of a_{Λ_φ} above appears as the effect of trivialization of the bundle $\Omega_{1/2} \otimes L$. Those Fourier integral operators whose associated conic Lagrangian manifolds are the graphs of \dagger homogeneous canonical transformations of $T^*(\mathbf{R}^n)$ are most frequently used in the theory of linear partial differential equations. Let A be a Fourier integral operator such that $\Lambda_\varphi(A)$ is the graph of a homogeneous canonical transformation χ . Then the adjoint of A is a Fourier integral operator such that the associated conic Lagrangian manifold is the graph of the inverse transformation χ^{-1} . Let A_1 be another such operator; if $\Lambda_\varphi(A_1)$ is the graph of χ_1 , then the composed operator $A_1 A$ is also a Fourier integral operator and $\Lambda_\varphi(A_1 A)$ is the graph of the composed homogeneous canonical transformation $\chi_1 \chi$.

Consider the kernel distribution $k(x, y)$ of A . If the phase function φ of A is nondegenerate, then $\text{WF}(k)$ is contained in $\Lambda_\varphi(A)$. Moreover, if the symbol $a_{\Lambda_\varphi}(A)$ does not vanish, then $\text{WF}(k) = \Lambda_\varphi(A)$. Let u be a distribution and A be a Fourier integral operator such that $\Lambda_\varphi(A)$ is the graph of a homogeneous canonical transformation χ . Then $\text{WF}(Au) \subset \chi(\text{WF}(u))$.

A pseudodifferential operator of class $S_{\rho,1-\rho}^m(\mathbf{R}^n)$ is a particular type of Fourier integral operator (\rightarrow 345 Pseudodifferential Operators). In fact, a Fourier integral operator A is a pseudodifferential operator of class $S_{\rho,1-\rho}^m(\mathbf{R}^n)$ if and only if $\Lambda_\varphi(A)$ is the graph of the identity mapping of $T^*(\mathbf{R}^n)$. Hence for any Fourier integral operator A , A^*A and AA^* are pseudodifferential operators.

The following theorem is due to Yu. V. Egorov [12]: Let $P(x, D)$ be a pseudodifferential operator of class $S_{\rho,1-\rho}^m(\mathbf{R}^n)$ with the symbol $p(x, \xi)$, and let A be a Fourier integral operator such that the associated conic Lagrangian manifold $\Lambda_\varphi(A)$ is the graph of a homogeneous canonical transformation χ of $T^*(\mathbf{R}^n)$. Then there exists a pseudodifferential operator $Q(x, D)$ with the symbol $q(x, \xi) \in S_{\rho,1-\rho}^m(\mathbf{R}^n)$ such that $P(x, D)A = AQ(x, D)$ and $q(x, \xi) - p(\chi(x, \xi)) \in S_{\rho,1-\rho}^{m-2\rho+1}(\mathbf{R}^n)$. Note that $m - 2\rho + 1 < m$.

Assume that $m = 1$, $\rho = 1$, and that $p_1(x, \xi)$ is a real-valued C^∞ -function, homogeneous of degree 1 in ξ for $|\xi| > 1$, such that $p(x, \xi) - p_1(x, \xi) \in S_{1,0}^0(\mathbf{R}^n)$ and $d_\xi p_1(x^0, \xi^0) \neq 0$ at (x^0, ξ^0) , where $p_1(x^0, \xi^0) = 0$. Then one can find a Fourier integral operator A such that the function $q(x, \xi)$ of Egorov's theorem satisfies the relation $q(x, \xi) - \xi_1 \in S_{1,0}^0(\mathbf{R}^n)$.

The boundedness of Fourier integral operators in the space $L_2(\mathbf{R}^n)$ (or the spaces $H^s(\mathbf{R}^n)$) has also been studied in several cases. Some sufficient conditions for boundedness can be found in [7, 8, 14–16].

The theory of Fourier integral operators has its origin in the asymptotic representation of solutions of the wave equation, (see, e.g., [17, 18]). Fourier integral operators were first used by G. I. Eskin [7].

D. Essential Support or Analytic Wave Front Set of a Distribution

Inspired by the physical idea introduced by C. Chandler and H. P. Stapp, J. Bros and D. Iagolnitzer introduced the notion of the **essential support** of a distribution, which is a closed subset of $X \times (\mathbf{R}^n \setminus 0)$ [19]. Let u be a distribution defined on an open set X of \mathbf{R}^n and χ be a C^∞ -function with compact support around $x_0 \in X$ which is locally analytic and different from 0 at x_0 . Let $\Sigma_\chi(u)$ be the subset of $\mathbf{R}^n \setminus 0$ of which the complement is defined as follows. A point η is in the complement of $\Sigma_\chi(u)$ if there exist a conic neighborhood U of η , constants $\alpha, \gamma_0 > 0$, and C_N such that

$$|\langle u, \chi \exp\{-ix'\xi - \gamma|\xi||x - x_0|^2\} \rangle| \leq C_N(1 + |\xi|)^{-N} e^{-\alpha\gamma|\xi|}$$

for all $\xi \in U$, $0 < \gamma < \gamma_0$, and all positive integers N .

The essential support $\Sigma_{x_0}(u)$ of u at x_0 , is the limit of $\Sigma_\chi(u)$ when the width $|\text{supp } \chi|$ of the support of χ around x_0 tends to 0. The **essential support** $\Sigma(u)$ of u is the closed subset $\bigcup_{x \in X} \{x\} \times \Sigma_x(u)$ of $X \times \mathbf{R}^n \setminus 0$. $\Sigma(u)$ is the obstruction for u to be real analytic. L. Hörmander [20] also defined the **analytic wave front set** of a distribution, which is also the obstruction for a distribution to be real analytic. The definition of an analytic wave front set is quite different from that of essential support. However they coincide with each other [21]. Moreover, both of them coincide with the singularity spectrum of u if the distribution u is regarded as a hyperfunction.

E. Microlocal Analysis for Hyperfunctions [22]

(1) Microfunctions. Let N be a real analytic manifold of dimension $n + d$ and M its submanifold of codimension d . In what follows, $T_M N$ and $T_M^* N$ denote the normal bundle of M and the conormal bundle supported by M , respectively. Here the **normal bundle** $T_M N$ is defined to be the quotient bundle $TN|_M / TM$ of the tangent bundle and the **conormal bundle** $T_M^* N$ to be the subbundle of the cotangent bundle $T^* N|_M$ that annihilates TM . Identifying N with $\{(x, v) \in TN | v = 0\}$ or $\{(x, \xi) \in T^* N | \xi = 0\}$, we define the **tangential sphere bundle** SN and **cotangential sphere bundle** $S^* N$ by $(TN \setminus N)/R_+^\times (= \bigcup_{x \in N} (T_x N \setminus \{0\})/R_+^\times)$ and $(T^* N \setminus N)/R_+^\times (= \bigcup_{x \in N} (T_x^* N \setminus \{0\})/R_+^\times)$, respectively. The **normal sphere bundle** $S_M N = (T_M N \setminus M)/R_+^\times$ and **conormal sphere bundle** $S_M^* N = (T_M^* N \setminus M)/R_+^\times$ are defined in the same manner. In parallel with the algebraic geometry (\rightarrow 16 Algebraic Varieties) we define the **real monoidal transform** of N with center M to be the manifold $(N \setminus M) \cup S_M N$ with boundary, in which the center M is blown up to $S_M N$ by the polar coordinates. We denote it by $\tilde{M}N$. We mainly use this notion when N is a \ast -complexification X of M , regarding X as a $2n$ -dimensional real manifold. In this case we can canonically identify $T_M X$ with $\sqrt{-1} TM$, and hence $S_M X$ with $\sqrt{-1} SM$. We denote by $x + \sqrt{-1}v \neq 0$ the point in $S_M X$ that corresponds to $(x, \sqrt{-1}v)$ in $\sqrt{-1} SM$ by this identification. An open subset W of $X \setminus M$ is called a **conoidal neighborhood** of a subset U of $\sqrt{-1} SM$ if $W \cup \sqrt{-1} SM$ is a neighborhood of U in $\tilde{M}X$. Let $\varepsilon, \tilde{\varepsilon}$, and $\tilde{\tau}$ denote respectively the canonical embedding mappings from $X \setminus M$ to X , from $\tilde{M}X \setminus \sqrt{-1} SM$ to $\tilde{M}X$ and from $\sqrt{-1} SM$ to $\tilde{M}X$. We then define the \ast -sheaves $\tilde{\mathcal{O}}$ and $\tilde{\mathcal{O}}'$

by $\tilde{e}_* \varepsilon^{-1} \mathcal{O}_X$ and $\tilde{\mathcal{O}}|_{\sqrt{-1}SM} (= \tilde{\tau}^{-1} \tilde{\mathcal{O}}_X)$. Here \mathcal{O}_X denotes the sheaf of germs of holomorphic functions on X . We also define the sheaf \mathcal{Q} on $\sqrt{-1}SM$ by $\mathcal{H}^1|_{\sqrt{-1}SM}(\tau^{-1}\mathcal{O}_X)$, where τ is the canonical projection from $\tilde{M}X$ to X and \mathcal{H}_S^p denotes the p th \dagger derived functor of the functor Γ_S of taking the sections with support in S . Then \mathcal{Q} is isomorphic to $\tilde{\mathcal{A}}/\tau^{-1}\mathcal{A}$ for the sheaf \mathcal{A} of real analytic functions on M . The sheaf $\tilde{\mathcal{A}}$ is, so to speak, the sheaf of "boundary values" of holomorphic functions. Actually there exists a canonical mapping b from $\tilde{\mathcal{A}}$ to $\tau^{-1}\mathcal{B}_M$, where \mathcal{B}_M denotes the sheaf of \dagger hyperfunctions on M (\rightarrow 125 Distributions and Hyperfunctions). Thus we see that \mathcal{Q} describes the singularities of the boundary value of a holomorphic function. These sheaves $\tilde{\mathcal{A}}$ and \mathcal{Q} are easy to understand intuitively. However, they are defined on $\sqrt{-1}SM$, while $\sqrt{-1}S^*M$ is more important in analysis. Our final goal, namely, the sheaf of microfunctions, is constructed on $\sqrt{-1}S^*M$ through cohomological machinery starting from \mathcal{Q} . In order to do this, we introduce the disk bundle DM by

$$\{(x + \sqrt{-1}v0, (x, \sqrt{-1}\xi\infty))$$

$$\in \sqrt{-1}SM \times_M \sqrt{-1}S^*M | \langle v, \xi \rangle \leq 0\}.$$

Here $\sqrt{-1}SM \times_M \sqrt{-1}S^*M$ denotes the \dagger fiber product of $\sqrt{-1}SM$ and $\sqrt{-1}S^*M$ over M and the symbol $\xi\infty$ is used to emphasize that ξ designates the codirection, which is dual to the infinitesimally small quantity $v0$. The canonical projections from DM to $\sqrt{-1}S^*M$ and from $\sqrt{-1}SM$ to M are both denoted by τ . Similarly, the projections from DM to $\sqrt{-1}SM$ and from $\sqrt{-1}S^*M$ to M are denoted by π . We denote by a the antipodal mapping on $\sqrt{-1}S^*M$, namely, $a(x, \sqrt{-1}\xi\infty) = (x, -\sqrt{-1}\xi\infty)$. For a sheaf \mathcal{F} on $\sqrt{-1}S^*M$, we also denote $a_*\mathcal{F} (= a^{-1}\mathcal{F})$ by \mathcal{F}^a . In the following, $R^j\tau_*$, etc., denotes the j th \dagger right-derived functor of the functor τ_* of taking the direct image of sheaves, etc. (\rightarrow 383 Sheaves). Now the sheaf \mathcal{C}_M of **microfunctions** is defined on $\sqrt{-1}S^*M$ by $(R^{n-1}\tau_*\pi^{-1}\mathcal{Q})^a \otimes \pi^{-1}\omega_M$, where ω_M denotes the \dagger orientation sheaf of M . Note that $R^j\tau_*\pi^{-1}\mathcal{Q} = 0$ holds for $j \neq n-1$.

Remark: Here we have defined the sheaf \mathcal{C}_M of microfunctions on $\sqrt{-1}S^*M$. However, it is sometimes more convenient to define the sheaf on $\sqrt{-1}T^*M (= T^*M)$ by the following convention: $\hat{\mathcal{C}}_{M,(x,\sqrt{-1}\xi)} = \mathcal{C}_{M,(x,\sqrt{-1}\xi\infty)}$ if $\xi \neq 0$, and $\mathcal{B}_{M,x}$, if $\xi = 0$. Several authors (e.g., [23]) call this sheaf $\hat{\mathcal{C}}_M$ the sheaf of microfunctions and denote it by \mathcal{C}_M .

(2) Basic Properties of Microfunctions. The sheaf \mathcal{C}_M defined above has the following properties: (i) The sheaf \mathcal{C}_M is a \dagger flabby sheaf

on $\sqrt{-1}S^*M$. (ii) For each $(x, \sqrt{-1}\xi\infty)$ in $\sqrt{-1}S^*M$, there exists a surjective mapping from $\mathcal{B}_{M,x}$ to $\mathcal{C}_{M,(x,\sqrt{-1}\xi\infty)}$. This mapping is denoted by sp . The mapping from \mathcal{B}_M to $\pi_*\mathcal{C}_M$ is also denoted by sp . (iii) We have the following exact sequence: $0 \rightarrow \mathcal{A}_M \rightarrow \mathcal{B}_M \xrightarrow{sp} \pi_*\mathcal{C}_M \rightarrow 0$. (iv) $R^k\pi_*\mathcal{C}_M = 0$ holds for $k \neq 0$. The exact sequence (iii) shows that the singularities of hyperfunctions are dispersed over $\sqrt{-1}S^*M$ and that the dispersed object is described by the sheaf \mathcal{C}_M of microfunctions. For a hyperfunction $f \in \mathcal{B}_M(M)$, we call $sp(f) \in \mathcal{C}(\sqrt{-1}S^*M)$ the **spectrum** of f . We denote $\text{supp } sp(f)$ by $S.S.f$ and call it the **singularity spectrum** of f or the **singular spectrum**. It is known [21] that this coincides with the analytic wave front set of f and with the essential support of f if f is a distribution. (v) The following sequence is an exact sequence on $\sqrt{-1}SM$: $0 \rightarrow \tilde{\mathcal{A}}_M \xrightarrow{b} \tau^{-1}\mathcal{B}_M \rightarrow \pi_*\tau^{-1}\mathcal{C}_M \rightarrow 0$. In the following, a subset A of the $(n-1)$ -dimensional sphere S^{n-1} is said to be convex if $\varpi^{-1}(A) \cup \{0\}$ is convex, where ϖ is the canonical projection from $\mathbb{R}^n \setminus \{0\}$ to S^{n-1} , and if $\varpi^{-1}(A) \cup \{0\}$ is convex and includes no straight line, A is said to be **properly convex**. A subset Z of $\sqrt{-1}SM$ (resp., $\sqrt{-1}S^*M$) is also said to be **(properly) convex** if $\tau^{-1}(x) \cap Z$ (resp., $\pi^{-1}(x) \cap Z$) is so for each x in M . For a subset Z of $\sqrt{-1}SM$ its polar set Z° is, by definition, $\{(x, \sqrt{-1}\xi\infty) \in \sqrt{-1}S^*M | \langle v_x, \xi_x \rangle > 0 \text{ holds for each } x + \sqrt{-1}v_x 0 \text{ in } Z\}$. The polar set Z° of a subset Z of $\sqrt{-1}S^*M$ is defined in the same way. (vi) Let U be an open subset of $\sqrt{-1}SM$ such that $\tau^{-1}(x) \cap U$ is a nonvoid connected set for each x in M . Let V denote $U^{\circ\circ}$. Then we have (a) The restriction mapping $\rho: \Gamma(V; \tilde{\mathcal{A}}) \rightarrow \Gamma(U; \tilde{\mathcal{A}})$ is a bijection. Here $\Gamma(V; \tilde{\mathcal{A}})$, etc. denotes the space of global sections of $\tilde{\mathcal{A}}$ over V , etc. (b) $0 \rightarrow \tilde{\mathcal{A}}(U) \rightarrow \mathcal{B}(M) \xrightarrow{sp} \mathcal{C}(\sqrt{-1}S^*M - U^\circ)$ is an exact sequence. (vii) Let $f(x)$ be a hyperfunction on M . Then the following two statements are equivalent: (a) $sp(f)_{(x_0, \sqrt{-1}\xi_0\infty)} = 0$. (b) There exist a finite family of open subsets U_j of $\sqrt{-1}SM$ whose polar set U_j° does not contain $(x_0, \sqrt{-1}\xi_0\infty)$ and φ_j in $\Gamma(U_j, \tilde{\mathcal{A}})$ such that $f = \sum_j b(\varphi_j)$. Then we say that f is **micro-analytic** at $(x_0, \sqrt{-1}\xi_0\infty)$.

(3) Operations on Microfunctions. Let M and N be real analytic manifolds, and let f be a real analytic mapping from N to M . We denote by T_N^*M the kernel of the natural mapping from $N \times_M T^*M$ to T^*N . It is also called a **conormal bundle supported by N** . The associated sphere bundle is denoted by S_N^*M . Denote by ρ and ϖ the natural mappings from $N \times_M \sqrt{-1}S^*M \setminus \sqrt{-1}S_N^*M$ to $\sqrt{-1}S^*N$ and from $N \times_M \sqrt{-1}S^*M \setminus \sqrt{-1}S_N^*M$ to $\sqrt{-1}S^*M$, respectively. (i) Let \mathcal{B}_M^* denote the

sheaf $\{u \in \mathcal{B}_M \mid \text{S.S. } u \cap \sqrt{-1} S_M^* M = \emptyset\}$. Then we have the following two canonical homomorphisms: $f^*: \mathcal{B}_M^* \rightarrow \mathcal{B}_N^*$ and $f^*: \mu_! \varpi^{-1} \mathcal{C}_M \rightarrow \mathcal{C}_N$. Here and in what follows, for a continuous mapping φ from N to M and a sheaf \mathcal{F} on N , $\varphi_! \mathcal{F}$ denotes the sheaf on M defined by assigning $\{s \in \Gamma(\varphi^{-1}(U); \mathcal{F}) \mid \varphi|_{\text{supp } s}: \text{supp } s \rightarrow U \text{ is } \dagger\text{proper}\}$ to each open subset U of M . These two homomorphisms are consistent. We call each of them a **substitution** (homomorphism) and denote it by $(f^* u)(y) = u(f(y))$. (ii) Let v_M denote the sheaf of \dagger densities. Then there exist the following two canonical homomorphisms: $f_*: f_!(\mathcal{B}_N \otimes_{\mathcal{B}_N} v_N) \rightarrow \mathcal{B}_M \otimes_{\mathcal{B}_M} v_M$ and $f_*: \varpi_! \rho^{-1}(\mathcal{C}_N \otimes_{\mathcal{C}_N} v_N) \rightarrow \mathcal{C}_M \otimes_{\mathcal{C}_M} v_M$. These two homomorphisms are consistent. We call each an **integration along a fiber** and denote it by $(f_* u)(x) = \int_{f^{-1}(x)} u$. (iii) Using the result in (i), we can define the **product** $u_1 u_2$ of two hyperfunctions u_1 and u_2 , if $\text{S.S. } u_1 \cap (\text{S.S. } u_2)^a = \emptyset$. Furthermore, the singularity spectrum of $u_1 u_2$ is contained in $\{(x, \sqrt{-1}(\theta \xi_1 + (1 - \theta) \xi_2) \infty) \mid (x, \sqrt{-1} \xi_1 \infty) \in \text{S.S. } u_1, (x, \sqrt{-1} \xi_2 \infty) \in \text{S.S. } u_2, 0 \leq \theta \leq 1\} \cup \text{S.S. } u_1 \cup \text{S.S. } u_2$.

F. Microdifferential Operators [22]

(1) Microlocal Operators. Let M be a real analytic manifold, and define the sheaf \mathcal{L}_M on $\sqrt{-1} S_M^*(M \times M) = \sqrt{-1} S^* M$ by $\mathcal{H}_{\sqrt{-1} S_M^*(M \times M)}^0(\mathcal{C}_{M \times M} \otimes v_M)$. A section $K(x, y)$ dy of \mathcal{L}_M naturally determines an integral operator $\mathcal{K}: u(y) \rightarrow \int K(x, y) u(y) dy$. An operator thus obtained is called a **microlocal operator**, because it acts on the sheaf \mathcal{C}_M of microfunctions as a sheaf homomorphism. Usually we identify an operator \mathcal{K} and a kernel function $K(x, y) dy$. (i) \mathcal{L}_M is a sheaf of rings by the natural composition. The unit element of \mathcal{L}_M is $\delta(x - y) dy$. It acts on \mathcal{C}_M as an identity operator. (ii) Let $K(x, y) dy$ be the kernel function of a microlocal operator \mathcal{K} defined near $(x_0, \sqrt{-1} \xi_0 \infty)$. Then its **adjoint operator** \mathcal{K}^* is, by definition, the microlocal operator defined near $(x_0, -\sqrt{-1} \xi_0 \infty)$ with the kernel function $K(y, x) dy$. The operation $*$ is a sheaf isomorphism between \mathcal{L}_M and \mathcal{L}_M^a , where a denotes the antipodal mapping (\rightarrow Section E).

(2) Microdifferential Operators. A microdifferential operator is an analog of a microlocal operator in the complex domain. By a procedure similar to that used to define the sheaf of microfunctions we first define the sheaf $\mathcal{C}_{Y|X}^\infty$ of **holomorphic microfunctions** for a submanifold Y of X (\rightarrow [22, definition 1.1.7 on p. 319], where it is denoted by $\mathcal{C}_{Y|X}$). It follows from the definition that $\mathcal{C}_{Y|X}^\infty$ is sup-

ported by $P_Y^*(Y \times X)$, which is identified with $Y \times_X P^* X$. Here and in what follows $P^* X$, etc., denotes the cotangential projective bundle of X , etc. Then the sheaf \mathcal{E}_X^∞ of **microdifferential operators (of infinite order)** is, by definition, $\mathcal{C}_{X|X \otimes X}^\infty \otimes_{\mathcal{C}_X} \Omega_X$, where Ω_X denotes the sheaf of holomorphic $\dim X$ -forms.

Remark. Several notations are used to denote \mathcal{E}_X^∞ in the literature. For example, [22] uses the symbol \mathcal{D}_X and calls it the sheaf of **pseudodifferential operators**. As in the case of microfunctions, some authors use the symbol \mathcal{E}_X^∞ to denote a sheaf on $T^* X$. In this case $\mathcal{E}_X^\infty|_X$ is, by definition, \mathcal{D}_X^∞ , the sheaf of linear differential operators (of infinite order). One should be careful in these notational confusions in referring to papers using microdifferential operators. We note also that the symbols \mathcal{D} and \mathcal{E} have nothing to do with the symbols in distribution theory.

We now list the basic properties of microdifferential operators.

(i) When X is a complexification of a real analytic manifold M , $\mathcal{E}_X^\infty|_{\sqrt{-1} S^* M}$ is a subring of \mathcal{L}_M .

(ii) Let Ω be an open subset of $P^* X$. Using a local coordinate system (x) on X , we define $\hat{\Omega}$ by $\{(x, \xi) \in \mathbb{C}^n \times (\mathbb{C}^n - \{0\}) \mid (x, \xi \infty) \in \Omega\}$. Let $\{p_j(x, \xi)\}_{j \in \mathbb{Z}}$ be a sequence of holomorphic functions on $\hat{\Omega}$ satisfying the following conditions: (1) $p_j(x, \xi)$ is homogeneous of degree j in ξ . (2) For each $\varepsilon > 0$ and each compact subset K of $\hat{\Omega}$, there exists a constant $C_{\varepsilon, K}$ such that $\sup_K |p_j(x, \xi)| \leq C_{\varepsilon, K} \varepsilon^{|j|} / j!$ ($j \geq 0$) holds. (3) For each compact subset K of $\hat{\Omega}$, there exists a constant R_K such that $\sup_K |p_j(x, \xi)| \leq R_K^{-j} (-j)! (j < 0)$ holds. Then there is a one-to-one correspondence between the space of such sequences and the space of sections of \mathcal{E}_X^∞ over Ω .

(iii) A sequence satisfying the conditions in (ii) is called a **symbol sequence**, and the corresponding section of \mathcal{E}_X^∞ is denoted by $\sum_{j \in \mathbb{Z}} p_j(x, D_x)$. If we define a subsheaf $\mathcal{E}_X(m)$ of \mathcal{E}_X^∞ by $\{P = \sum_j p_j(x, D_x) \in \mathcal{E}_X^\infty \mid p_j(x, \xi) = 0 (j \geq m + 1)\}$, it is independent of the choice of the local coordinate systems. A microdifferential operator belonging to $\mathcal{E}_X(m)$ is said to be of **order** (at most) m . We denote $\bigcup_m \mathcal{E}_X(m)$ by \mathcal{E}_X and call a section of \mathcal{E}_X a **microdifferential operator of finite order**.

(iv) Let $\Phi_\lambda(z)$ denote $\Gamma(\lambda)/(-z)^\lambda$, where its branch is chosen so that $\Phi_\lambda(-1) = \Gamma(\lambda)$. When $\lambda = 0, -1, -2, \dots$, we consider its \dagger finite part. Let Ω be a complex neighborhood of $(x_0, \sqrt{-1} \xi_0 \infty) \in \sqrt{-1} S^* \mathbb{R}^n \cong \mathbb{R}^n \times \sqrt{-1} S^{n-1}$. Using a symbol sequence $\{p_j(z, \xi)\}$ on $\hat{\Omega}$, we define a multivalued holomorphic function $K(z, w, \zeta)$ by $\sum_j p_j(z, \zeta) \Phi_{n+j}(\langle z - w, \zeta \rangle)$ and consider its boundary value from the domain

$\text{Re}\langle z-w, \xi \rangle < 0$. We denote the resulting microfunction by

$$\sum_j p_j(x, \sqrt{-1} \xi) \Phi_{n+j}(\sqrt{-1}(\langle x-y, \xi \rangle + \sqrt{-1} 0)).$$

Then

$$K(x, y) = (2\pi)^{-n} \int \left\{ \sum_j p_j(x, \sqrt{-1} \xi) \Phi_{n+j}(\langle x-y, \sqrt{-1} \xi \rangle - 0) \right\} \omega(\xi)$$

is a well-defined microfunction in a neighborhood of $(x_0, x_0; \sqrt{-1}(\xi_0, -\xi_0)\infty)$ whose support is contained in the antidiagonal set $\Delta^a = \{(x, y; \sqrt{-1}(\xi, \eta)\infty) \in \sqrt{-1}S^*(M \times M) | x=y, \xi+\eta=0\}$. Here $\omega(\xi)$ is the volume element of the $(n-1)$ -dimensional sphere S^{n-1} . Hence $K(x, y)dy$ defines a microlocal operator. The mapping which associates $K(x, y)dy$ with $\{p_j(x, \xi)\}$ is compatible with the inclusion mapping stated in (i).

(v) By using the \dagger plane wave decomposition of the δ -function due to F. John (\rightarrow 125 Distributions and Hyperfunctions CC), we find that microdifferential operators are a natural generalization of linear differential operators: A linear differential operator corresponds to a symbol sequence $\{p_j(x, \xi)\}_{j \geq 0}$, where p_j is a polynomial with respect to ξ .

(vi) (a) Let $P = \sum_j p_j(x, D_x)$ and $Q = \sum_k q_k(x, D_x)$ be microdifferential operators. Then their composition $R = P \circ Q$ is a microdifferential operator with the symbol sequence $\{r_l\}_{l \in \mathbb{Z}}$ given by

$$r_l(x, \xi) = \sum_{i=j+k-|a|} \frac{1}{\alpha!} D_\xi^a p_j(x, \xi) D_x^a q_k(x, \xi).$$

Here $D_\xi^a = \partial^{|\alpha|} / \partial \xi_1^{\alpha_1} \dots \partial \xi_n^{\alpha_n}$ and $\alpha! = \alpha_1! \dots \alpha_n!$ for the \dagger multi-index $\alpha = (\alpha_1, \dots, \alpha_n)$. (b) Let $P = \sum_j p_j(x, D_x)$ be a microdifferential operator. Let $\delta(x-y)$ denote the residue class $[1]$ of the left $\mathcal{E}_{X \times X}$ -Module $\mathcal{E}_{X \times X} / (\sum_{k=1}^n \mathcal{E}_{X \times X}(x_k - y_k) + \sum_{k=1}^n \mathcal{E}_{X \times X}(\partial/\partial x_k + \partial/\partial y_k))$. ("Module" means sheaf of modules.) Then there exists a unique microdifferential operator $R = \sum_l r_l(y, D_y)$ such that $P(x, D_x)\delta(x-y) = R(y, D_y)\delta(x-y)$. Furthermore, $r_l(x, \xi)$ is given by

$$\sum_{l=j-|a|} \frac{(-1)^j}{\alpha!} D_\xi^a D_x^a p_j(x, \xi).$$

R is called the **adjoint operator** of P and is denoted by P^* . When X is a complexification of the real manifold M , it coincides with the adjoint operator $P^* \in \mathcal{L}_M^a$.

(vii) For a microdifferential operator P in $\mathcal{E}_X(m)$, we define its **principal symbol** $\sigma_m(P)$ by $p_m(x, \xi)$. The principal symbol $\sigma_m(P)$ is in-

dependent of the choice of local coordinate system. It gives an isomorphism between $\mathcal{E}_X(m)/\mathcal{E}_X(m-1)$ and $\mathcal{O}_{T^*X}(m)$, the sheaf of holomorphic functions on T^*X which are homogeneous of degree m with respect to ξ .

(viii) (a) Let P be in $\mathcal{E}_X(m)_{(x_0, \xi_0)}$. Assume that $\sigma_m(P)(x_0, \xi_0) \neq 0$. Then its inverse P^{-1} (i.e., $PP^{-1} = P^{-1}P = 1$) exists in $\mathcal{E}_X(-m)_{(x_0, \xi_0)}$. (b) Let P and G be in $\mathcal{E}_X(m)_{(x_0, \xi_0)}$, $\mathcal{E}_X(l)_{(x_0, \xi_0)}$, respectively. Suppose that $H_{\sigma_f(G)}^j(\sigma_m(P))(x_0, \xi_0) = 0$ ($j=0, \dots, p-1$) and that $H_{\sigma_f(G)}^p(\sigma_m(P))(x_0, \xi_0) \neq 0$. (Here $H_f(g)$ is, by definition, the \dagger Poisson bracket $\{f, g\}$ of f and g (\rightarrow 82 Contact Transformations)). Then for each S in $\mathcal{E}_{X, (x_0, \xi_0)}$ we can find Q and R in $\mathcal{E}_{X, (x_0, \xi_0)}$ so that $S = QP +$

R with $(\text{ad } G)^p R \stackrel{\text{def}}{=} [\overbrace{G, \dots, G}^p, [G, R], \dots] = 0$ holds. This result is usually referred to as the **Sp ath-type division theorem (for microdifferential operators)**. In particular, when $G = x_n$ and $(x_0, \xi_0) = (0; 1, 0, \dots, 0)$, R has the form $\sum_{k=0}^{p-1} R^{(k)}(x, D') D_n^k$. Here $R^{(k)}(x, D') = R^{(k)}(x, D_1, \dots, D_{n-1})$. As a corollary to this expression we find the following (**Weierstrass-type preparation theorem (for microdifferential operators)**): Let P be as above, and let $G = x_n$. Then we can find Q and W in $\mathcal{E}_{X, (0; 1, 0, \dots, 0)}$ such that $P = QW$ with invertible Q and $W = D_n^p + \sum_{k=0}^{p-1} W^{(k)}(x, D') D_n^k$, where $W^{(k)}$ belongs to $\mathcal{E}_X(p-k)$ and $\sigma_{p-k}(W^{(k)})(0; 1, 0, \dots, 0) = 0$.

(ix) **Quantized contact transformation.** (a) Let X be an n -dimensional complex manifold and Ω an open subset of P^*X . Let P_j ($j=1, 2, \dots, n$) be in $\mathcal{E}_X(1)(\Omega)$ and Q_j ($j=1, \dots, n$) in $\mathcal{E}_X(0)(\Omega)$. Assume that $[P_j, P_k] = [Q_j, Q_k] = 0$ and $[P_j, Q_k] = \delta_{jk}$ hold ($1 \leq j, k \leq n$). Let φ be the contact transformation from Ω to $P^*\mathbb{C}^n$ defined by $p \mapsto (\sigma_0(Q_1)(p), \dots, \sigma_0(Q_n)(p), \sigma_1(P_1)(p), \dots, \sigma_1(P_n)(p))$. Then there exists a unique \mathbb{C} -algebra homomorphism $\Phi: \varphi^{-1}\mathcal{E}_{\mathbb{C}^n} \rightarrow \mathcal{E}_X|_\Omega$ such that $\Phi(x_j) = Q_j$ and $\Phi(D_j) = P_j$ ($j=1, \dots, n$). Furthermore, Φ is an isomorphism, $\Phi\mathcal{E}_{\mathbb{C}^n}(m) = \mathcal{E}_X(m)$ holds, and $\sigma_m(\Phi(R)) = \sigma_m(R) \circ \varphi$ holds for R in $\mathcal{E}_{\mathbb{C}^n}(m)$. We call the pair (φ, Φ) a **quantized contact transformation**. In the above situation, the $\mathcal{E}_{X \times \mathbb{C}^n}$ -Module

$$\mathcal{M} = \mathcal{E}_{X \times \mathbb{C}^n} / \left(\sum_{j=1}^n \mathcal{E}_{X \times \mathbb{C}^n}(x_j - Q_j) + \sum_{j=1}^n \mathcal{E}_{X \times \mathbb{C}^n}(-D_j - P_j) \right)$$

is a simple holonomic system (\rightarrow Section H) whose support is the graph of φ^a . Let u be the canonical generator of \mathcal{M} , i.e., the residue class of 1 in \mathcal{M} . Then $R^*u = \Phi(R)u$ holds for $R \in \mathcal{E}_{\mathbb{C}^n}$. (b) Conversely, let φ be a contact transformation from a neighborhood of p in P^*X to $P^*\mathbb{C}^n$, and let u be a generator of a simple holonomic system whose support is the graph

of φ^a . Then a \mathbb{C} -algebra isomorphism $\Phi: \varphi^{-1}\mathcal{E}_{\mathbb{C}^n} \rightarrow \mathcal{E}_X$ is defined in a neighborhood of p through $R^*u = \Phi(R)u$ ($R \in \mathcal{E}_{\mathbb{C}^n}$), and (φ, Φ) becomes a quantized contact transformation. (c) In particular, let p be a point in $\sqrt{-1} S^*M$ and Ω its complex neighborhood. Let (φ, Φ) be a real quantized contact transformation defined on Ω (i.e., φ maps $\sqrt{-1} S^*M$ to $\sqrt{-1} \cdot S^*\mathbf{R}^n$). Then, in a neighborhood of $(p, \varphi(p)^a) \in \sqrt{-1} S^*(M \times \mathbf{R}^n)$, there exists a microfunction solution $K(y, x) \neq 0$ of the equations $x_j K(y, x) = Q_j K(y, x)$, $-(\partial/\partial x_j) K(y, x) = P_j K(y, x)$ ($j = 1, \dots, n$) ($x \in \mathbf{R}^n, y \in M$). Such a microfunction is unique up to constant multiple. The integral operator $\mathcal{K}: v(x) \mapsto \int K(y, x)v(y)dy$ gives rise to a sheaf isomorphism between $\varphi^{-1}\mathcal{E}_{\mathbf{R}^n}$ and \mathcal{E}_M in a neighborhood of p . Furthermore, we have $\mathcal{K}(Rv) = \Phi(R)(\mathcal{K}v)$ for $v \in \mathcal{E}_{\mathbf{R}^n}$ and $R \in \mathcal{E}_{\mathbb{C}^n}$. This \mathcal{K} is the counterpart of the Fourier integral operator (\rightarrow Section C).

(x) Algebraic properties of \mathcal{E}_X^∞ and \mathcal{E}_X . (a) \mathcal{E}_X is \dagger coherent as a left \mathcal{E}_X -Module, and its stalk is a \dagger left Noetherian ring. (b) \mathcal{E}_X^∞ is \dagger faithfully flat over \mathcal{E}_X . (c) \mathcal{E}_X is \dagger flat over $\mathcal{E}_X(0)$. (d) \mathcal{E}_X is flat over $\pi^{-1}\mathcal{Q}_X$.

G. Microdifferential Equations [22, 24]

(1) **Background.** A system \mathcal{M} of **microdifferential equations** (of finite order) is by definition a \dagger coherent left (or right) \mathcal{E}_X -Module, i.e., there exists locally an exact sequence of the form $\mathcal{E}_X^p \rightarrow \mathcal{E}_X^q \rightarrow \mathcal{M} \rightarrow 0$. For a coherent \mathcal{E} -Module \mathcal{M} , the support $\text{Supp } \mathcal{M}$ of \mathcal{M} is an important geometric object associated with \mathcal{M} . It is called the **characteristic variety** of \mathcal{M} . For a coherent \mathcal{D} -Module \mathcal{M} , its characteristic variety is by definition $\text{Supp}(\mathcal{E} \otimes_{\mathcal{D}} \mathcal{M})$. It is often denoted by $\text{S.S. } \mathcal{M}$. Since a microdifferential operator is a microlocal operator, the result in (viii) (a) of Section F (3) asserts that $\mathcal{E}xt_{\mathcal{E}}^j(\mathcal{M}, \mathcal{E}_M)$ is supported by the characteristic variety of M intersected with $\sqrt{-1} S^*M$. Now, it is known that $V = \text{Supp } \mathcal{M}$ is \dagger involutive (= involutive, in involution) in P^*X , namely, $f|_V = g|_V = 0$ entails $\{f, g\}|_V = 0$ [22, theorem 5.3.2 on p. 453]. One of the most important problems in microlocal analysis is to study how much information V can give concerning the structure of \mathcal{M} itself, and hence that of $\mathcal{E}xt_{\mathcal{E}}^j(\mathcal{M}, \mathcal{E}_M)$. The epoch-making discovery of [22] is that V determines the structure of $\mathcal{E}^\infty \otimes_{\mathcal{E}} \mathcal{M}$ at generic points of V as follows.

(2) **Structure Theorems.** The fundamental result of [22, theorem 5.3.7 on p. 455] is the following theorem for coherent \mathcal{E} -Modules:

Structure theorem 1. Let \mathcal{M} be a coherent \mathcal{E}_X -Module satisfying the following conditions:

(1) $\mathcal{E}xt_{\mathcal{E}_X}^j(\mathcal{M}, \mathcal{E}_X) = 0$ for $j \neq d$. (2) $V \stackrel{\text{def}}{=} \text{Supp } \mathcal{M}$ is **regular** at $p \in V$ in the sense that V is non-singular near p and that $\omega|_V(p) \neq 0$ for the \dagger canonical 1-form ω . Then, through a quantized contact transformation (φ, Φ) , $\mathcal{E}^\infty \otimes \mathcal{M}$ is isomorphic to a direct summand of a direct sum of finite copies of **partial de Rham system** $\mathcal{N}_0 = \mathcal{E}^\infty_{\mathbb{C}^n} / (\sum_{j=1}^d \mathcal{E}^\infty_{\mathbb{C}^n} \partial/\partial z_j)$ with $\varphi(p) = (0; 0, \dots, 0, 1) \in P^*\mathbb{C}^n$.

By studying the canonical form of V under real contact transformations, [22] further gives the following structure theorem in a real domain, i.e., in $\sqrt{-1} S^*M$ for a real analytic manifold M .

Structure theorem 2. Let X be a complexification of a real analytic manifold M , and let \mathcal{M} be as in structure theorem 1. Let p be a point in $V \cap \sqrt{-1} S^*M$. Suppose that the following three conditions are satisfied: (3) $V \cap \bar{V}$ is regular at p . (4) $T_q(V) \cap T_q(\bar{V}) = T_q(V \cap \bar{V})$ holds for each q in $V \cap \bar{V}$. Here \bar{V} denotes the complex conjugate of V (with respect to $\sqrt{-1} S^*M$) and $T_q(V)$, etc., denotes the tangent space of V , etc., at q . (5) The generalized Levi form of V is of constant \dagger signature (a, b) near p , where the **generalized Levi form** of V is, by definition, the Hermitian form

$$L(v) = \sum_{j,k} \{p_j, \bar{p}_k\}(x, \sqrt{-1} \xi) v_j \bar{v}_k$$

for the p_j such that $V = \bigcap_j p_j^{-1}(0)$. Then $\mathcal{E}^\infty \otimes \mathcal{M}$ is isomorphic to a direct summand of a direct sum of finite copies of the system $\mathcal{E}^\infty \otimes_{\mathcal{E}} \mathcal{N}$ considered in a neighborhood of $(x, \sqrt{-1} \xi) = (0, \sqrt{-1}(0, \dots, 0, 1)) \in \sqrt{-1} S^*\mathbf{R}^n$, where \mathcal{N} is given by

$$\begin{aligned} \frac{\partial}{\partial x_j} f &= 0 \quad (j = 1, \dots, r), \\ \left(\frac{\partial}{\partial x_{r+2k-1}} + \sqrt{-1} \frac{\partial}{\partial x_{r+2k}} \right) f &= 0 \quad (k = 1, \dots, s), \\ \left(\frac{\partial}{\partial x_{r+2s+l}} + \sqrt{-1} x_{r+2s+l} \frac{\partial}{\partial x_n} \right) f &= 0 \\ &\quad (l = 1, \dots, a), \\ \left(\frac{\partial}{\partial x_{r+2s+l}} - \sqrt{-1} x_{r+2s+l} \frac{\partial}{\partial x_n} \right) f &= 0 \\ &\quad (l = a+1, \dots, a+b). \end{aligned}$$

Here, $r = 2 \text{codim } V - \text{codim}(V \cap \bar{V})$ and $s = \text{codim}(V \cap \bar{V}) - \text{codim } V - (a+b)$.

The first (resp. second) type of equation in the above are called (partial) **de Rham equations** (resp. (partial) **Cauchy-Riemann equations**). The third and the fourth are called **Lewy-Mizohata equations** (of type (a, b)) after these authors' pioneering works [25, 26]. Thus any system is seen to be microlocally isomorphic to a mixture of these three types of equations, generically speaking. As a corollary to

this, structure theorem 2 clarifies the structure of microfunction solutions of \mathcal{M} as follows:

Structure theorem 3. Let M, X, \mathcal{M}, V , and p be as in structure theorem 2. Then $\mathcal{E}x_{\mathcal{E}_X}^j(\mathcal{E}_X^\alpha \otimes \mathcal{M}, \mathcal{E}_M) = 0$ ($j \neq \alpha$) holds, and the remaining cohomology group $\mathcal{F} = \mathcal{E}x_{\mathcal{E}_X}^a(\mathcal{E}_X^\alpha \otimes \mathcal{M}, \mathcal{E}_M)$ has the following structure in a neighborhood U of p : There exists an s -dimensional complex manifold Y , a real analytic manifold N , and a † smooth mapping φ from $V \cap U \cap \sqrt{-1} S^*M$ to $Y \times \sqrt{-1} S^*N$ such that $\mathcal{F} = \varphi^{-1} \mathcal{G}$ for a sheaf \mathcal{G} on $Y \times \sqrt{-1} S^*N$ that is a direct summand of \mathcal{H}^N , with \mathcal{H} being the solution sheaf of the partial Cauchy-Riemann equations associated with Y .

H. Holonomic Systems

A coherent (left) \mathcal{E} -Module \mathcal{M} is called **holonomic** if $\text{Supp } \mathcal{M}$ is † Lagrangian. A coherent (left) \mathcal{D} -Module \mathcal{M} is called holonomic if $\mathcal{E} \otimes_{\mathcal{D}} \mathcal{M}$ is so. Even though the term "holonomic" is currently used, another term, "**maximally overdetermined**," is used to describe the same object in some of the literature, including [22]. The importance of such a system lies in the fact that the space of its microfunction solutions is finite-dimensional [27, 29]. In this sense it resembles an ordinary differential equation. A holonomic system, however, does not satisfy condition (2) of structure theorem 1 of Section G, and its structure is rather complicated. A result which corresponds to structure theorem 1 in Section G is the following: Let V be an involutory submanifold of T^*X , and let \mathcal{E}_V be the subring of \mathcal{E}_X generated by $\{P \in \mathcal{E}_X(1) \mid \sigma_1(P)|_V = 0\}$. Then a coherent \mathcal{E}_X -Module \mathcal{M} defined on an open subset Ω of T^*X is said to have **regular singularities** along V if for any point p of Ω , there exist a neighborhood U of p and an \mathcal{E}_V -sub-Module \mathcal{M}_0 of \mathcal{M} defined on U which is coherent over $\mathcal{E}(0)$, and which generates \mathcal{M} as an \mathcal{E}_X -Module. A holonomic system is said to have R.S., which is an abbreviation for regular singularities, if it has R.S. along its support. Then for an arbitrary holonomic \mathcal{E} -Module \mathcal{M} we can find a holonomic \mathcal{E} -Module \mathcal{M}_{reg} with R.S. such that $\mathcal{E}^\infty \otimes_{\mathcal{E}} \mathcal{M}_{\text{reg}} \cong \mathcal{E}^\infty \otimes_{\mathcal{E}} \mathcal{M}$ holds. See [28] for the proof of this striking result and related topics on **holonomic systems with regular singularities**.

An elementary class of holonomic systems is that of **simple holonomic systems**. A holonomic \mathcal{E} -Module \mathcal{M} is called simple if there exists a left Ideal \mathcal{I} such that $\mathcal{M} = \mathcal{E}/\mathcal{I}$ and that the symbol Ideal $\{\sigma(P) \mid P \in \mathcal{I}\}$ coincides with the defining Ideal of $\text{Supp } \mathcal{M}$. Let u denote the generator $1 \bmod \mathcal{I}$ of a simple holonomic

system \mathcal{E}/\mathcal{I} . Suppose that $\Lambda = \text{Supp } \mathcal{M}$ is nonsingular. Then the **principal symbol** $\sigma_\Lambda(u)$ is defined as follows: For $P = \sum_j p_j(x, D_x) \in \mathcal{I}(m)$, let L_p denote the first-order linear differential operator

$$L_p = H_{p_m(x, \xi)} + \left(p_{m-1}(x, \xi) - \frac{1}{2} \sum_i \frac{\partial^2 p_m(x, \xi)}{\partial x_i \partial \xi_i} \right).$$

Here, H_{p_m} denotes the Hamiltonian vector field defined by $\{p_m, \cdot\}$. Let Ω_Λ and Ω_X denote the sheaf of n -forms of Λ and X , respectively, and let $\Omega_\Lambda^{\otimes 1/2}$ (resp. $\Omega_\Lambda^{\otimes 1/2} \otimes \Omega_X^{\otimes -1/2}$) denote a line bundle L such that $L^{\otimes 2}$ is isomorphic to Ω_Λ (resp. $\Omega_\Lambda \otimes \Omega_X^{\otimes -1}$). Since the line bundles $\Omega_\Lambda^{\otimes 1/2}$ and $\Omega_\Lambda^{\otimes 1/2} \otimes \Omega_X^{\otimes -1/2}$ do not exist globally in general, all the equations among their sections should be understood up to a constant multiplicative factor. When Λ is a purely imaginary Lagrangian submanifold of $\sqrt{-1} S^*M$ for a real analytic manifold M , these line bundles can be constructed globally by using the Keller-Maslov index (\rightarrow Section C). Let v and ψ denote respectively the first term and the second term in the right-hand side of the above definition of L_p . Then $\tilde{L}_p: \Omega_\Lambda^{\otimes 1/2} \rightarrow \Omega_\Lambda^{\otimes 1/2}$ is given by $\tilde{L}_p(s) = (1/2s)L_v(s^2) + \psi s$ for $s \in \Omega_\Lambda^{\otimes 1/2}$, where $L_v(s^2)$ denotes the † Lie derivative of s^2 along v . One can then prove that the system of equations $\tilde{L}_p s = 0$ ($P \in \mathcal{I}$) admits locally one and exactly one nonzero solution s in $\Omega_\Lambda^{\otimes 1/2}$ up to a constant factor. Then the principal symbol $\sigma_\Lambda(u)$ of u equals $s \otimes \sqrt{dx} \in \Omega_\Lambda^{\otimes 1/2} \otimes \Omega_X^{\otimes -1/2}$ by definition. The principal symbol $\sigma_\Lambda(u)$ is homogeneous with respect to ξ , and its homogeneous degree is called the **order** of u and is denoted by $\text{ord}_\Lambda(u)$. The microlocal structure of a simple holonomic \mathcal{E} -Module with a nonsingular characteristic variety is determined by the order of its generator as follows: (a) Let $\mathcal{E}u$ and $\mathcal{E}v$ denote simple holonomic \mathcal{E} -Modules with the same characteristic variety Λ . Then $\mathcal{E}u$ is isomorphic to $\mathcal{E}v$ if and only if $\text{ord}_\Lambda(u) - \text{ord}_\Lambda(v)$ is an integer. (b) Let $\mathcal{E}u$ be a simple holonomic system, and let α denote the order of u . Then through a suitable quantized contact transformation, $\mathcal{E}u$ is isomorphic to $\mathcal{E}_{C^n} w$, where w satisfies

$$\left(z_1 \frac{\partial}{\partial z_1} + \left(\alpha + \frac{1}{2} \right) \right) w = 0,$$

$$\frac{\partial w}{\partial z_j} = 0 \quad (j = 2, \dots, n).$$

Thus the microlocal structure of a simple holonomic system $\mathcal{M} = \mathcal{E}u$ is fairly simple at nonsingular points of its characteristic variety. Moreover a Hartogs-type theorem for micro-differential equations [28, ch. I, §2] entails that if $\text{Supp } \mathcal{M}$ has the form $\Lambda_1 \cup \Lambda_2$ with Lagrangian manifolds Λ_1 and Λ_2 such that

Microlocal Analysis

$\text{codim}_{\Lambda_1}(\Lambda_1 \cap \Lambda_2) \geq 2$; then \mathcal{M} has the form $\mathcal{M}_1 \oplus \mathcal{M}_2$ with $\text{supp } \mathcal{M}_j = \Lambda_j$ ($j = 1, 2$). Hence the case where $\text{codim}_{\Lambda_1}(\Lambda_1 \cap \Lambda_2) = 1$ is important. Suppose Λ_1 and Λ_2 are nonsingular in this case and $T_x \Lambda_1 \neq T_x \Lambda_2$ at a point $x \in \Lambda_1 \cap \Lambda_2$. Then, through a quantized contact transformation (ψ, Φ) , the system \mathcal{M} is isomorphic to \mathcal{E}_{C^*w} , with w satisfying the following equations defined near $(0; dz_1, \infty)$:

$$\left(z_1 \frac{\partial}{\partial z_1} + \left(\alpha_1 + \frac{1}{2} \right) \right) w = 0,$$

$$\left(z_2 \frac{\partial}{\partial z_2} + \left(\alpha_1 - \alpha_2 + \frac{1}{2} \right) \right) w = 0,$$

$$\frac{\partial w}{\partial z_j} = 0 \quad (j = 3, \dots, n),$$

where $\alpha_j = \text{ord}_{\Lambda_j}(u)$ ($j = 1, 2$) with $\psi(\Lambda_1) = \{z_1 = 0, \xi_2 = \dots = \xi_n = 0\}$ and $\psi(\Lambda_2) = \{z_1 = z_2 = 0, \xi_3 = \dots = \xi_n = 0\}$. For more general cases and an application \rightarrow [30].

The theory of holonomic systems and its applications are being studied most intensively, raising the hope of establishing a unified theory of special functions of several variables; \rightarrow [23] and references cited therein.

I. History

Microlocal analysis means local analysis on the cotangent bundle. It emphasizes the importance of localization in cotangent bundles in analysis, which was pointed out by S. Mizohata [5, 6] immediately after the advent of singular integral operators in the works of A. P. Calderón and A. Zygmund [3, 4]. Since then, localization in the cotangent bundle has been used frequently in the theory of linear partial differential equations. R. T. Seeley [31] proved that the symbol of a singular integral operator is well defined on the cotangent bundle. Works by J. J. Kohn and L. Nirenberg [32] and L. Hörmander (*Comm. Pure Appl. Math.*, 18 (1965)) strengthened the trend of localizing the problem on the cotangent bundle. Although it seems that the term "microlocal analysis" first appeared in the literature in 1973 (T. Kawai, *Astérisque*, 2 and 3 (1973)), the basic part of the theory had been constructed during the period from 1969 to 1972 by M. Sato (*Proc. Intern. Conf. Functional Anal. and Related Topics*, 1969), Yu. V. Egorov [12], Hörmander [8, 20], J. J. Duistermaat and Hörmander (*Acta Math.*, 128 (1972)), M. Kashiwara and Kawai (*Proc. Japan Acad.*, 46 (1970)), and Sato, Kawai, and Kashiwara [22]. Apparently the work of V. P. Maslov [11] had an important influence on the work of Egorov. The most important part of Sato's

contribution was the fact that, through the construction of the sheaf of microfunctions he found that the singularities of hyperfunctions can be canonically dispersed over the cotangent bundle (\rightarrow Section E) and that a hyperfunction solution u of a linear differential equation $Pu = 0$ is concentrated on the characteristic variety when its singularities are thus dispersed (\rightarrow Section G). The last-stated fact was also formulated by Hörmander [8, 20] in the framework of distribution theory. The most important part of the contribution of Egorov [12] was the discovery that one can use an integral transformation introduced by V. I. Eskin [7] to find a transformation of pseudodifferential operators compatible with a homogeneous canonical transformation, i.e., a contact transformation, so that the commutation relations and the orders of the operators can be preserved. Hörmander (*Acta Math.*, 121 (1969)) independently introduced integral transformations of the same type, calling them Fourier integral operators. Egorov [13] and L. Nirenberg and F. Trèves [33] successfully used the transformation of operators to study the regularity and existence of solutions. Subsequently, Hörmander [8] elaborated the theory of Fourier integral operators. Kashiwara and Kawai (*Proc. Japan Acad.*, 46 (1970)) observed that a pseudodifferential operator in their sense (now called a microdifferential operator; \rightarrow Section F) gives rise to a sheaf homomorphism on the sheaf of microfunctions and that the structure of the microfunction solutions of pseudodifferential equations is determined by the principal symbol of the operator in question if it has simple characteristics. Then Sato, Kawai, and Kashiwara [22] succeeded in amalgamating these two theories, namely, the theory of microfunctions and the theory of the transformation of operators. (They called the transformation a quantized contact transformation in [22]). Such an amalgamation was also done independently by Hörmander [8, 20], who introduced the notion of the wave front set for distributions as a substitute for the support of microfunctions. Incidentally, it is noteworthy that C. Chandler and H. P. Stapp (*J. Math. Phys.*, 10 (1969)) and D. Iagolnitzer and Stapp (*Comm. Math. Phys.*, 14 (1969)) obtained a notion similar to the singularity spectrum in a physical context. Their results were later elaborated (around 1971–1973) by J. Bros and Iagolnitzer [19]. With the aid of the above-mentioned amalgamation of the theories, the works of Sato, Kawai, and Kashiwara [22], Hörmander [20], Duistermaat and Hörmander (*Acta Math.*, 121 (1969)), Kawai (*Publ. Res. Inst. Math. Sci.*, 7 (1971–1972)) and K. G. Andersson (*Trans. Amer. Math. Soc.*, 177 (1973)) have clarified the

importance of the bicharacteristic strip, which is a submanifold of a cotangent bundle, not a base manifold, as a carrier of singularities of solutions of pseudodifferential equations (\rightarrow Section G); and the works of Sato, Kawai, and Kashiwara [22], Sato (*Actes Congr. Internat. Math. Nice*, 1971) and Kawai (*Publ. Res. Inst. Math. Sci.*, 7 (1971–1972)) revealed the hidden mechanism of the celebrated counterexample of H. Lewy [25]. Among these, the contribution of Sato, Kawai, and Kashiwara [22] was most decisive and fundamental in that it first clarified the structure of a general system of pseudodifferential equations at generic points of the characteristic variety and then derived from it the above-quoted results on the structure of the solutions (\rightarrow Section G).

Microlocal analysis has now become one of the most important and basic concepts in the theory of linear partial differential equations and theoretical physics. For recent developments \rightarrow Hörmander [34] and V. Guillemin, Kashiwara, and Kawai [23] and references cited therein.

275 (VII.14) Minimal Submanifolds

A. General Remarks

An immersion f of an m -dimensional manifold M with boundary ∂M (possibly empty) into a Riemannian manifold N is called **minimal** if the †mean curvature vector field H of M with respect to the induced Riemannian metric vanishes identically. Then M is called a **minimal submanifold** of N . This definition comes from the following variational problem: By a smooth †variation of f is meant a smooth mapping $F: I \times M \rightarrow N$, where $I = (-1, 1)$, such that each $f_t = F(t, \cdot): M \rightarrow N$ is an immersion, $f_0 = f$, and $f_t|_{\partial M} = f|_{\partial M}$ for all $t \in I$. Let dV_t be the volume element of the metric induced by f_t , and set $V(t) = \int_M dV_t$, the volume of M at time t . Then the first variation of the volume is expressed as

$$\left. \frac{dV}{dt} \right|_{t=0} = -m \int_M \left\langle H, F_* \frac{\partial}{\partial t} \right|_{t=0} \rangle dV_0,$$

where $\partial/\partial t$ denotes the canonical vector field along the I factor in $I \times M$. Thus the mean curvature vector field H of f vanishes identically if and only if $dV/dt|_{t=0} = 0$ for all variations of f . Therefore a minimal submanifold gives an extremal of the volume integral, though neither necessarily minimal nor of the least volume.

In the case $N = \mathbf{R}^n$, an immersion $x: M \rightarrow \mathbf{R}^n$ is viewed as a vector-valued function, and the mean curvature vector field H is expressed as $H = \Delta x/m$, where Δ denotes the †Laplace-Beltrami operator $-g^{ij} \nabla_i \nabla_j$. Thus x is minimal if and only if each component function of x is harmonic. In particular, there is no compact minimal submanifold without boundary in \mathbf{R}^n .

The history of the theory of minimal submanifolds goes back to J. L. Lagrange, who studied minimal surfaces in the 3-dimensional Euclidean space \mathbf{R}^3 . In 1762 he developed his algorithm for the †calculus of variations, which can be applied to higher-dimensional problems and is now known as the †Euler-Lagrange equation. For instance, let D be a domain in the plane \mathbf{R}^2 and $z = f(x, y)$, $(x, y) \in D$, the equation of a surface in \mathbf{R}^3 . As a necessary condition for the surface to have the least area among the surfaces with fixed boundary, Lagrange obtained a †quasilinear elliptic partial differential equation of the second order, called the **minimal surface equation**:

$$(1 + z_y^2)z_{xx} - 2z_x z_y z_{xy} + (1 + z_x^2)z_{yy} = 0.$$

Before this, in 1744, L. Euler had found that a †catenoid is a minimal surface. In 1766, J. B. M. C. Meusnier showed that a right †helicoid is a minimal surface. Besides catenoids and helicoids, in 1834, H. F. Scherk found that the surface defined by $z = \log(\cos y) - \log(\cos x)$ is a minimal surface, which is called **Scherk's surface**.

In the latter half of the 19th century, †Plateau's problem (\rightarrow Section C; 334 Plateau's Problem) was studied extensively by O. Bonnet, B. Riemann, K. Weierstrass, A. Enneper, G. Darboux, and others. The problem is stated as follows: Given a †Jordan curve Γ in \mathbf{R}^3 (or in \mathbf{R}^n), find a surface of least area having Γ as its boundary. On the other hand, in 1866, Weierstrass gave a general formula, called the **Weierstrass-Enneper formula** (\rightarrow Section B (5)), to express a simply connected minimal surface in terms of a complex analytic function and a meromorphic function with certain properties. The formula allows one to construct a great variety of minimal surfaces by choosing those functions.

The existence of a minimal surface of disk type having a prescribed boundary curve was first obtained in 1930 by J. Douglas and T. Radó independently as a solution to Plateau's problem, admitting singularities. The result was improved by R. Courant for the case of finitely many boundary curves by the method of †Dirichlet integrals. The method was carried out further by C. B. Morrey for the generalized Plateau's problem in a Riemannian manifold (\rightarrow Section C (5)). Indeed, the Euclidean space was replaced by any complete Riemannian manifold which is metrically well behaved at infinity. For example, any compact or any †homogeneous Riemannian manifold is in this class.

The existence proof of minimal surfaces cannot in general be applied directly to the case of higher-dimensional minimal submanifolds. The notion of varifolds (\rightarrow Section G (2))

and the corresponding generalization of a minimal submanifold, called a minimal variety (\rightarrow Section G (2)), were then introduced by F. Almgren, who proved the existence of a minimal variety in a compact Riemannian manifold. It was also proved that a minimal variety is approximated by regular minimal submanifolds. This work has been developed as geometric measure theory by E. R. Reifenberg, W. H. Fleming, H. Federer, F. Almgren, and others (\rightarrow Section G).

The study of minimal surfaces given as the graph of a real-valued function of two variables leads to that of solutions of the minimal surface equation. In 1915, S. Bernstein proved that a minimal surface $z = f(x, y)$ defined on the entire plane \mathbf{R}^2 must be a plane. Subsequently, this was generalized to the following problem: Is a minimal hypersurface $x_{n+1} = f(x_1, \dots, x_n)$ in \mathbf{R}^{n+1} defined on the entire space \mathbf{R}^n a hyperplane? The answer turns out to be affirmative for $n \leq 7$ and negative for $n \geq 8$ (\rightarrow Section F (1)).

In general, when a bounded domain D in \mathbf{R}^n and a continuous function φ on its boundary ∂D are given, the problem of finding a minimal hypersurface M defined by the graph of a real-valued function f on \bar{D} with $f|_{\partial D} = \varphi$ gives rise to a typical \dagger Dirichlet problem. The basic questions are those of existence, uniqueness, and regularity of solutions. These were first studied by Radó for $n = 2$ and later by L. Bers, R. Finn, H. Jenkins, J. Serrin, R. Osserman, and others (\rightarrow Section D (1)).

Minimal submanifolds of a sphere have interesting properties; some are analogous to those in Euclidean space but some are not. Among them, J. Simons, in 1968, gave a differential equation that the norm of the second fundamental form of a minimal submanifold in a sphere should satisfy. He then showed that a totally geodesic submanifold is isolated among the compact minimal submanifolds in the sphere. S. S. Chern, M. P. do Carmo, S. Kobayashi, N. Ejiri, T. Ito, T. Otsuki, N. Wallach, and others have made further contributions to this subject (\rightarrow Section F (2)).

B. Minimal Surfaces

(1) **Branched minimal surfaces.** A minimal surface M in \mathbf{R}^n is an immersed surface with vanishing mean curvature vector field. M equipped with an atlas of \dagger isothermal coordinates is viewed as a \dagger Riemann surface. A **branch point** of a \dagger harmonic mapping $f: M \rightarrow \mathbf{R}^n$ is a point at which the differential df_p is zero. A harmonic mapping $f: M \rightarrow \mathbf{R}^n$ of a Riemann surface M is called a **branched** (or

generalized) **minimal immersion** if it is conformal except at the branch points, and the image $f(M)$ is then called a **branched minimal surface**. The solution to Plateau's problem given by Douglas and Radó is a branched minimal surface.

(2) **Maximum principle.** When $n = 3$, the following maximum principle for minimal surfaces holds: If M_1 and M_2 are two connected branched minimal surfaces in \mathbf{R}^3 such that for a point $p \in M_1 \cap M_2$, the surface M_1 locally lies on one side of M_2 near p , then M_1 and M_2 coincide near p .

(3) **Convex hull property.** In general, every branched minimal surface with boundary in \mathbf{R}^n lies in the **convex hull** of its boundary curve, the smallest closed convex set containing the boundary.

(4) **Reflection principle.** If the boundary curve of a branched minimal surface contains a straight line γ , then the surface can be analytically continued as a branched minimal surface by reflection across γ . Based on this principle, the following holds: Let Γ be an analytic Jordan curve in \mathbf{R}^n and $f: M \rightarrow \mathbf{R}^n$ a branched minimal immersion with boundary Γ . Then f is analytic up to the boundary, i.e., $f(M)$ is contained in the interior of a larger branched minimal surface (H. Lewy). The smooth version of this theorem was given by S. Hildebrandt: If $f: M \rightarrow \mathbf{R}^n$ is a branched minimal immersion with smooth boundary curve, then f is smooth up to the boundary.

(5) **Weierstrass-Enneper formula.** Every simply connected minimal surface in \mathbf{R}^3 is represented in the form

$$x_k(\zeta) = \operatorname{Re} \left\{ \int_0^\zeta \phi_k(z) dz \right\} + c_k, \quad k = 1, 2, 3,$$

where $\phi_1 = f(1 - g^2)/2$, $\phi_2 = \sqrt{-1} f(1 + g^2)/2$, $\phi_3 = fg$, and c_k is a constant. Here, $g(\zeta)$ is a meromorphic function on a domain D in the complex ζ -plane, and $f(\zeta)$ is an analytic function on D with the property that at each point ζ , where $g(\zeta)$ has a pole of order m , $f(\zeta)$ has a zero of order $2m$, D being either the unit disk or the entire plane. This formula is quite useful for constructing various minimal surfaces. For instance, on setting $f \equiv 1$ and $g(\zeta) = \zeta$, **Enneper's surface** is obtained:

$$(x_1, x_2, x_3) = \left(u - \frac{u^3}{3} + uv^2, v - \frac{v^3}{3} + vu^2, u^2 - v^2\right), \\ (u, v) \in \mathbf{R}^2.$$

Another feature of the formula is that general theorems about minimal surfaces can be obtained by translating statements about analytic functions into the corresponding minimal-surface ones. For example, a surface $f: M \rightarrow \mathbf{R}^3$ is minimal if and only if the \dagger Gauss mapping

$G: M \rightarrow S^2$ is **antiholomorphic**, i.e., the complex conjugate of the mapping is holomorphic, when S^2 is viewed as the Riemann sphere with complex structure by the stereographic projection (from the south pole) onto the complex plane. As a consequence, a complete minimal surface in \mathbf{R}^3 is a plane or else the normals to the surface are everywhere dense in S^2 (R. Osserman).

(6) **Stability.** A minimal submanifold M is called **stable** if for every compact region on M all the second variations of the volume are positive. For instance, if $M \rightarrow \mathbf{R}^n$ is a minimal hypersurface and $f\nu$ is a variation vector field, ν being the unit normal vector field of M and f a smooth function with compact support on M , then the second variation formula for the volume $V(t)$ is given by

$$\left. \frac{d^2 V}{dt^2} \right|_{t=0} = \int_M (|\nabla f|^2 - |A|^2 f^2) dv_0,$$

where $|A|$ denotes the norm of the second fundamental form of M . In particular, when $n=3$, then $-|A|^2/2=K$, the Gauss curvature of M . Therefore a minimal surface M in \mathbf{R}^3 is stable if and only if

$$\int_M (|\nabla f|^2 + 2Kf^2) dV > 0$$

for any smooth function f with compact support on M . It follows that the stability of minimal surface M in \mathbf{R}^3 is related to the boundary value problem of a linear elliptic operator $L = \Delta - 2K$, Δ being the Laplacian on M .

Namely, a minimal surface M in \mathbf{R}^3 is stable if and only if the first eigenvalue $\lambda_1(D)$ of L on any bounded domain D in M is nonnegative.

In connection with the \dagger Gauss mapping, a sufficient condition for a domain D in a minimal surface to be stable was obtained by H. Schwarz in 1885: If a minimal surface M in \mathbf{R}^3 has one-to-one Gauss mapping $G: M \rightarrow S^2$, then a domain $D \subset M$ such that $G(D)$ is contained in a hemisphere of S^2 is stable. This was generalized by J. L. Barbosa and M. do Carmo as follows: If the area $A(G(D))$ of the spherical image $G(D)$ is less than 2π , then D is stable.

This result is sharp in the sense that for any $\varepsilon > 0$ there exists an unstable domain D with $A(G(D)) = 2\pi + \varepsilon$. As an analog to Bernshtein's theorem, the following holds: A complete and stable minimal surface in \mathbf{R}^3 is a plane. H. Mori has also obtained results in this regard.

As for the existence of unstable minimal surfaces, it is known that if there are two distinct stable minimal surfaces with the same smooth boundary curve Γ in \mathbf{R}^3 , then there exists an unstable branched minimal surface with Γ as its boundary (M. Morse and C. Tompkins, M. Schiffman).

C. Plateau's Problem (\rightarrow 334 Plateau's Problem)

Let Γ be a \dagger rectifiable \dagger Jordan curve in \mathbf{R}^n and $D = \{(x, y) \in \mathbf{R}^2 \mid x^2 + y^2 < 1\}$. Then there exists a continuous mapping $f: \bar{D} \rightarrow \mathbf{R}^n$ such that (a) $f|_{\partial D}$ maps homeomorphically onto Γ ; (b) $f|_D$ is harmonic and **almost conformal**, i.e., $\langle f_x, f_y \rangle = 0$ and $|f_x| = |f_y|$ in D with $|df| > 0$ except at isolated branch points; (c) the induced area of f is the least among the class of piecewise smooth surfaces bounding Γ with (a). This mapping f is called the **classical solution** or the **Douglas-Radó solution** to Plateau's problem for Γ , which may have singularities called \dagger branch points. The resulting surface S is a branched minimal disk. This theorem establishes the existence of a surface of least area among all surfaces homeomorphic to a disk. It has been generalized by R. Courant for Γ consisting of finitely many rectifiable Jordan curves.

For a branched minimal disk S bounded by smooth Γ in \mathbf{R}^3 , there is a relation, called the **Gauss-Bonnet-Sasaki-Nitsche formula**, among the \dagger total curvature $\kappa(\Gamma)$ of Γ , the total curvature of S , and the orders of branch points:

$$1 + \sum (m_x - 1) + \sum M_\beta + \frac{1}{2\pi} \int_S |K| dA \leq \frac{1}{2\pi} \kappa(\Gamma),$$

where K denotes the Gauss curvature of S , $m_x - 1$ the orders of the interior branch points, and $2M_\beta$ the orders of the boundary branch points, which must be even.

(1) **Regularity.** A minimal disk of least area in \mathbf{R}^3 has no boundary branch points when Γ is real analytic (R. Gulliver and F. Leslie) or when Γ is smooth and the total curvature $\kappa(\Gamma)$ is less than 4π (J. C. C. Nitsche). In general, a classical solution for smooth Γ in \mathbf{R}^3 cannot have infinitely many branch points. A remarkable fact is that every classical solution to Plateau's problem in \mathbf{R}^3 is free of branch points in its interior, i.e., is a regular immersion (R. Osserman).

(2) **Embeddedness.** A classical solution is not necessarily an embedding; it may have self-intersections. For instance, if Γ is knotted in \mathbf{R}^3 , then every solution must have self-intersections. It is known, however, that immersed minimal disks of least area in \mathbf{R}^3 which can self-intersect only in their interiors are embeddings. In particular, if Γ is an **extremal** Jordan curve, i.e., if Γ lies on the boundary of its \dagger convex hull, then the classical solution for Γ is an embedding (F. Tomi and A. J. Tromba; W. H. Meeks and S. T. Yau). If the topological type is not specified, then there always exists an embedded minimal surface. That is, if Γ is the union of any finite collection of disjoint

smooth Jordan curves in \mathbf{R}^3 , then there exists a compact embedded minimal surface with boundary Γ which is smooth up to the boundary (R. Hardt and L. Simon). However, there exists an unknotted Jordan curve that never bounds an embedded minimal disk.

(3) **Uniqueness.** In general, the classical solutions to Plateau's problem do not have the uniqueness property. Radó was the first who gave a condition on a boundary curve to guarantee the uniqueness of the minimal disk. Namely, if a Jordan curve Γ in \mathbf{R}^n admits a one-to-one orthogonal projection onto a convex curve in a plane \mathbf{R}^2 in \mathbf{R}^n , then the classical solution to Plateau's problem for Γ is free of branch points and can be expressed as the graph over this plane. When $n=3$, the solution is unique. Another geometric condition on Γ has been given by Nitsche: An analytic Jordan curve Γ in \mathbf{R}^3 with total curvature $\kappa(\Gamma) \leq 4\pi$ (or a smooth Γ with $\kappa(\Gamma) < 4\pi$) bounds a unique immersed minimal disk. Moreover, the generic uniqueness holds: In the space \mathcal{A} of all smooth Jordan curves in \mathbf{R}^n with suitable topology, there exists an open and dense subset \mathcal{B} such that for any Γ in \mathcal{B} there exists a unique area-minimizing minimal disk (F. Morgan and A. J. Tromba).

(4) **Finiteness.** As for the finiteness of the classical solutions to Plateau's problem, several conditions on boundary curves are known. An analytic Jordan curve in \mathbf{R}^3 bounds only finitely many minimal disks of least area (F. Tomi). An analytic extremal Jordan curve in \mathbf{R}^3 bounds only finitely many minimal disks with relative minima of area (H. Beeson). A smooth Jordan curve Γ with total curvature $\kappa(\Gamma) \leq 6\pi$ bounds only finitely many minimal disks (Nitsche). Moreover, generically, i.e., for an open and dense subset of boundary curves, there are at most finitely many minimal surfaces with given boundary, relative minima or not (R. Böhme and Tromba).

(5) **Generalized Plateau's problem.** C. B. Morrey's setting of the generalized Plateau's problem is as follows: A homotopically trivial rectifiable Jordan curve Γ is given in an n -dimensional Riemannian manifold N . Let D denote a disk in \mathbf{R}^2 . Find a mapping $f: \bar{D} \rightarrow N$ such that (a) $f|_{\partial D}$ maps homeomorphically onto Γ , (b) the induced area of f is the least among the class of piecewise smooth surfaces in N bounded by Γ with (a). Obviously when $N = \mathbf{R}^n$, this is the classical Plateau's problem. A solution was given by Morrey under the assumption that N is **homogeneously regular**; i.e., that there exist $0 < k < K$ such that for any point $y \in N$ there is a local coordinate system (V, Φ) around y for which $\Phi(V) = \{x \in \mathbf{R}^n | \|x\| < 1\}$ and the Riemannian metric

$\sum g_{\alpha\beta} dx^\alpha dx^\beta$ satisfies

$$k \sum (v^\alpha)^2 \leq \sum g_{\alpha\beta} v^\alpha v^\beta \leq K \sum (v^\alpha)^2$$

for any x and $(v_1, \dots, v_n) \in \mathbf{R}^n$. Any compact or any homogeneous Riemannian manifold is homogeneously regular. Morrey's solution is as follows: If N is a homogeneously regular Riemannian manifold and if Γ is a homotopically trivial rectifiable Jordan curve in N , then there exists a branched minimal immersion $f: D \rightarrow N$ with least area bounded by Γ with (a).

The regularity of Morrey's solution is similar to the classical one. If Γ is smooth, then so is the solution f up to the boundary. If, furthermore, $\dim N = 3$, then the solution f is an immersion in its interior. If N and Γ are real analytic and $\dim N = 3$, then the solution f is an immersion up to the boundary.

D. Existence Problems of Minimal Submanifolds

(1) **The Dirichlet problem for the minimal surface equation.** When the graph of a (vector-valued) function is a minimal submanifold in some Euclidean space, the function must satisfy the so-called †minimal surface equation. To be precise, let D be a (bounded) domain in \mathbf{R}^n , $f: D \rightarrow \mathbf{R}^k$ a (vector-valued) function, and put $F: D \rightarrow \mathbf{R}^{n+k}$: $F(x) = (x, f(x))$ for $x \in D$. Let M be the graph of f : $M = F(D)$. Then M is minimal if and only if f (or F) satisfies one of the following equations:

if $n=2$ and $k=1$,

$$(1 + f_y^2)f_{xx} - 2f_x f_y f_{xy} + (1 + f_x^2)f_{yy} = 0; \quad (1)$$

if n is arbitrary and $k=1$,

$$\sum_{i=1}^n \frac{\partial}{\partial x^i} \left(\frac{1}{W} \frac{\partial f}{\partial x^i} \right) = 0 \quad \text{where} \quad W = \sqrt{1 + |\nabla f|^2}; \quad (2)$$

if $n=2$ and k is arbitrary,

$$(1 + |f_y|^2)f_{xx} - 2(f_x \cdot f_y)f_{xy} + (1 + |f_x|^2)f_{yy} = 0; \quad (3)$$

and if n and k are arbitrary,

$$\sum_{i,j=1}^n g^{ij} \frac{\partial^2 f}{\partial x^i \partial x^j} = 0 \quad \text{where} \quad g_{ij} = \frac{\partial F}{\partial x^i} \cdot \frac{\partial F}{\partial x^j}, \quad (4)$$

and (g^{ij}) is the inverse matrix of (g_{ij}) .

The basic problem for this class of equations is the †Dirichlet problem. For $n=2$ and $k=1$, the following theorem of Radó and Finn is fundamental: There exists a solution f of the Dirichlet problem corresponding to an arbitrary continuous function φ on the boundary ∂D of D if and only if D is convex. Since the difference of any two solutions of eq. (1) satisfies the maximum principle, there can be at most one solution f of the Dirichlet problem

corresponding to a given continuous function φ on ∂D . As for the removability of isolated singularities, the following is known: Every solution of eq. (1) in $0 < x^2 + y^2 < 1$ extends continuously to the origin. The extended function is smooth at the origin and satisfies eq. (1) in the full disk $x^2 + y^2 < 1$ (Finn).

For arbitrary n and $k = 1$, namely, for the case of minimal hypersurfaces, the following is known: Let D be a bounded domain in \mathbf{R}^n with smooth boundary. The Dirichlet problem for eq. (2) has a solution for any continuous function φ on ∂D if and only if the mean curvature of ∂D with respect to the inner normal is non-negative at every point. As for the uniqueness and regularity, the same results as above hold (Jenkins and Serrin).

For $n = 2$ and arbitrary k , namely, for the case of minimal surfaces in \mathbf{R}^{2+k} , exactly the same result of existence as in the classical case $k = 1$ holds. A solution exists for an arbitrary continuous vector-valued function on ∂D if and only if D is convex (Osserman). Though the removability of singularities holds under suitable restrictions, the uniqueness fails in this case.

For the last case, $n > 2$ and $k > 1$, there are essentially no results on either existence or uniqueness for the Dirichlet problem.

(2) **Existence of minimal surfaces and topology.** For a compact Riemannian manifold N , there are results on the existence of minimal surfaces related to the homotopy groups of N . Let f be a continuous mapping from a \dagger Riemann surface Σ_g of \dagger genus g into N . If the \dagger induced mapping $f_\# : \pi_1(\Sigma_g) \rightarrow \pi_1(N)$ of f on the \dagger fundamental groups is injective, then there exists a branched minimal immersion $h : \Sigma_g \rightarrow N$ such that $h_\# = f_\#$ on $\pi_1(\Sigma_g)$ and the induced area of h is the least among all mappings with the same action on $\pi_1(\Sigma_g)$. If furthermore $\pi_2(N) = 0$, then h can be deformed from f continuously (R. Schoen and S. T. Yau). If $\pi_2(N) \neq 0$, then there exists a generating set for $\pi_2(N)$ consisting of branched minimal immersions of spheres that minimize energy and area in their homotopy classes (J. Sacks and K. Uhlenbeck). If, furthermore, $\dim N = 3$, then the above minimal immersion h in the homotopy class is an embedding or a two-to-one covering mapping. In the second case, its image is an embedded real projective plane. If h' is another such least-area mapping, then either h' is equal to h up to a conformal reparametrization or the images of h and h' are disjoint (Meeks and Yau).

E. Gauss Mapping of Minimal Surfaces

On a connected, orientable surface M there exist local isothermal coordinates (x, y) at each

point. On putting $z = x + \sqrt{-1} y$, the metric has the form $ds^2 = 2F|dz|^2$, and M is viewed as a Riemann surface. A conformal immersion $f : M \rightarrow \mathbf{R}^n$ is minimal if and only if $\Delta f = 0$, or equivalently $\partial_z \partial_{\bar{z}} f = 0$. In the case $n = 3$, the \dagger Gauss mapping $G : M \rightarrow S^2$ of a surface $f : M \rightarrow \mathbf{R}^3$ is defined by assigning to each point $p \in M$ the unit normal vector translated parallel to the origin of \mathbf{R}^3 . A surface $f : M \rightarrow \mathbf{R}^3$ is minimal if and only if the Gauss mapping is antiholomorphic. In the general case, the Gauss mapping G is defined to be a mapping assigning to each point $p \in M$ the oriented tangent space $f_* T_p(M) \subset \mathbf{R}^n$. Thus G is a mapping from M into the \dagger Grassmann manifold $\tilde{M}_{n,2}(\mathbf{R}) = SO(n)/SO(2) \times SO(n-2)$ of oriented planes in \mathbf{R}^n , which is naturally diffeomorphic to the \dagger complex quadric Q_{n-2} in the complex projective space \mathbf{CP}^{n-1} . An immersion $f : M \rightarrow \mathbf{R}^n$ is minimal if and only if its Gauss mapping is antiholomorphic.

Let $f : M \rightarrow \mathbf{R}^n$ be a complete orientable minimal surface. Let χ be the Euler characteristic and $-\pi C = \int_M K dA$, the total curvature of $f(M)$. Assume that the total curvature is finite. Then the following results of Chern and Osserman are fundamental: (a) M is conformally a compact Riemann surface \bar{M} with finite number, say r , of points deleted; (b) C is an even integer and satisfies $C \geq 2(r - \chi) = 4g + 4r - 4$, where g is the genus of M ($=$ genus of \bar{M}); (c) if $f(M)$ does not lie in any proper affine subspace of \mathbf{R}^n , then $C \geq 4g + r + n - 3 \geq 4g + n - 2 \geq n - 2$ (F. Gackstatter); (d) if $f(M)$ is simply connected and nondegenerate, i.e., its image under the Gauss mapping does not lie in a hyperplane of \mathbf{CP}^{n-1} , then $C \geq 2n - 2$ and this inequality is sharp; (e) when $n = 3$, C is a multiple of 4, with the minimum value 4 attained only for Enneper's surface and the catenoid; (f) the Gauss mapping G of M extends to a mapping of \bar{M} whose image $G(\bar{M})$ is an algebraic curve in \mathbf{CP}^{n-1} lying in Q_{n-2} ; the total curvature of $f(M)$ is equal in absolute value to the area of $G(\bar{M})$, counting multiplicity; (g) $G(M)$ intersects a fixed number of times, say m (counting multiplicity), every hyperplane in \mathbf{CP}^{n-1} except for those hyperplanes containing any of the finite number of points of $G(\bar{M} - M)$; the total curvature of $f(M)$ equals $-2\pi m$.

In particular, if a complete minimal surface in \mathbf{R}^n has k \dagger ends, then the total curvature never exceeds $2\pi(\chi - k)$. Enneper's surface and the catenoid are the only two complete minimal surfaces in \mathbf{R}^3 whose Gauss mapping is one-to-one.

If the Gauss mapping of a complete minimal surface of finite total curvature in \mathbf{R}^3 omits more than 3 points of S^2 , then it is a plane (Osserman). F. Xavier proved that the Gauss mapping of any complete nonflat minimal

surface in \mathbf{R}^3 can omit at most 6 points of S^2 . It is an open question whether this can be improved to 4 points. The Gauss mapping of Scherk's surface omits exactly 4 points of S^2 .

F. Minimal Submanifolds

(1) **Bernshtein's problem.** As was mentioned in Section A, a minimal surface in \mathbf{R}^3 represented as the graph of a function on the entire plane \mathbf{R}^2 is a plane. This is known as **Bernshtein's theorem** (1915). This is, however, not true in \mathbf{R}^4 , namely, there is a minimal surface defined as the graph of a vector-valued function on the entire plane, which is not a plane. The **generalized Bernshtein problem** is stated as follows: Let $f: \mathbf{R}^n \rightarrow \mathbf{R}$ be a function satisfying the minimal hypersurface equation

$$\sum_{i=1}^n \frac{\partial}{\partial x^i} \left(\frac{1}{W} \frac{\partial f}{\partial x^i} \right) = 0,$$

where $W = \sqrt{1 + |\nabla f|^2}$. Is the graph of f an affine hyperplane? The answer is affirmative for $n \leq 7$ (E. De Giorgi, F. J. Almgren, J. Simons). For $n \geq 8$, it is negative (E. Bombieri, De Giorgi, E. Giusti). Though the problem turns out to be negative for $n \geq 8$, no concrete counterexample is known, even for $n = 8$.

(2) **Minimal submanifolds in the sphere.** Minimal submanifolds in the unit sphere S^n have some special properties. For example, there is no compact minimal submanifold of S^n contained in an open hemisphere. On the other hand, there is no stable minimal closed submanifold in S^n (B. Lawson, Simons). More generally, any closed minimal hypersurface in a Riemannian manifold with positive Ricci curvature is unstable (Simons). As for the existence of minimal surfaces in a sphere, the following theorem of Lawson is general: Any closed surface of any genus, except the real projective plane, can be minimally immersed into the unit sphere S^3 . As an analog to Bernshtein's theorem, a sphere S^2 , which is minimally immersed in S^3 , is necessarily totally geodesic. On the other hand, by making use of higher-order second fundamental forms and the relations among them, a complete description of the minimal immersions of \mathbf{R}^2 into S^n has been given by K. Kenmotsu.

As a general theorem which gives a necessary and sufficient condition for a Riemannian manifold to be minimally immersed in the unit sphere S^n , the following is fundamental: An isometric immersion x of an m -dimensional Riemannian manifold M into S^n , viewed as a vector-valued function into \mathbf{R}^{n+1} , is minimal if and only if $\Delta x = mx$ (T. Takahashi). As its immediate application, any m -dimensional compact homogeneous space whose linear

isotropy group is irreducible can be minimally immersed into the n -sphere of curvature λ/m , corresponding to any eigenvalue ($\neq 0$) of the Laplacian, where $n+1$ is the dimension of the eigenspace corresponding to λ (W. Y. Hsiang, Takahashi).

Since for the k -symmetric spaces of rank 1 the eigenvalues and the corresponding eigenspaces of the Laplacian are known, the minimal immersions of such spaces into the unit sphere have been determined as well as the rigidity of such minimal immersions (N. Wallach). For example, if the m -sphere of constant curvature c is minimally immersed into the unit n -sphere, but not contained in any great hypersphere, then for each nonnegative integer k , $c = m/k(k+m-1)$ and $n+1 \leq (2k+m-1) \cdot [(k+m-2)!/k!(m-1)!]$. The immersion is rigid if and only if $m=2$ or $k \leq 3$. Similar results have been known for the projective spaces over real numbers, complexes, quaternions, or Cayley numbers.

Simons showed that the scalar curvature ρ of a compact minimal submanifold M of dimension m in the unit $(m+p)$ -sphere is not greater than $m(m-1)$. Furthermore, if $\rho \geq m(m-1) - mp/(2p-1)$, then either $\rho = m(m-1)$ or $\rho = m(m-1) - mp/(2p-1)$. In the former case, M is totally geodesic and therefore is the unit sphere S^m . In the latter case, M is either a hypersurface of the unit $(m+1)$ -sphere which is isometric to the product $S^k(\sqrt{k/m}) \times S^{m-k}(\sqrt{(m-k)/m})$ of spheres of radius $\sqrt{k/m}$ and $\sqrt{(m-k)/m}$, respectively, called the **generalized Clifford torus** or the **Veronese surface** in S^4 . Here the **Clifford torus** is the torus $S^1(\sqrt{1/2}) \times S^1(\sqrt{1/2}) \subset S^3 \subset \mathbf{R}^4$, and the Veronese surface is defined as follows: Let (x, y, z) be the natural coordinate system in \mathbf{R}^3 and $(u^1, u^2, u^3, u^4, u^5)$ that in \mathbf{R}^5 . The mapping defined by

$$\begin{aligned} u^1 &= yz/\sqrt{3}, & u^2 &= zx/\sqrt{3}, & u^3 &= xy/\sqrt{3}, \\ u^4 &= (x^2 - y^2)/2\sqrt{3}, & u^5 &= (x^2 + y^2 - 2z^2)/6 \end{aligned}$$

gives an isometric immersion of $S^2(\sqrt{3})$ into S^4 . Two points (x, y, z) and $(-x, -y, -z)$ of $S^2(\sqrt{3})$ are mapped into the same point of S^4 , and thus the mapping defines an embedding of the real projective plane \mathbf{RP}^2 into S^4 . This embedded real projective plane in S^4 is called the Veronese surface.

T. Otsuki proved the following: Let M be a complete minimal hypersurface immersed in the unit $(n+1)$ -sphere with two principal curvatures. If their multiplicities are m and $n-m \geq 2$, then M is congruent to the generalized Clifford torus $S^m(\sqrt{m/n}) \times S^{n-m}(\sqrt{(n-m)/n}) \subset S^{n+1} \subset \mathbf{R}^{n+2}$. If one of their multiplicities is 1, then M is a hypersurface of S^{n+1} in $\mathbf{R}^{n+2} = \mathbf{R}^n \times \mathbf{R}^2$ whose orthogonal projection into \mathbf{R}^2

Minimal Submanifolds

is a curve of which the †support function $x(t)$ is a solution of the following nonlinear differential equation of the second order:

$$nx(1-x^2)(d^2x/dt^2) + (dx/dt)^2 + (1-x^2)(nx^2-1) = 0.$$

Furthermore, there are countably many compact minimal hypersurfaces immersed but not embedded in S^{n+1} . Only $S^{n-1}(\sqrt{(n-1)/n}) \times S^1(\sqrt{1/n})$ is minimally embedded in S^{n+1} . This just corresponds to the trivial solution $x(t) \equiv 1/\sqrt{n}$ of the above equation.

(3) **Minimal submanifolds in Riemannian manifolds.** In general, it is difficult to determine all the complete stable minimal submanifolds in a given Riemannian manifold. If, however, some curvature conditions are given to the Riemannian manifold, then a classification has been given: Let N be a complete 3-dimensional Riemannian manifold with non-negative scalar curvature ρ , and let M be a complete, stable, and orientable minimal surface in N .

(a) If M is compact, then either M is conformally equivalent to the †Riemann sphere S^2 or else it is a totally geodesic flat torus. Furthermore, if $\rho > 0$, then the latter case never occurs.

(b) If M is not compact, then M is conformally equivalent to the complex plane \mathbb{C} or a cylinder (D. Fischer Colbrie; R. Schoen).

As a generalization of the procedure for generating periodic minimal surfaces in \mathbb{R}^3 with octahedral or tetrahedral symmetry (Schwarz, 1867), T. Nagano and B. Smyth gave a construction procedure to generate periodic minimal surfaces in \mathbb{R}^n or n -tori with symmetry corresponding to any †Weyl group of rank n .

G. Minimal Varieties

Recent progress in the study of Plateau's problem in higher dimensions is closely related to the point of view of geometric measure theory and †the calculus of variations.

(1) **Integral currents.** Let T be a †current of degree k , or simply a k -current, defined on an open set U of \mathbb{R}^n , and let ∂T be the boundary of T , the exterior derivative of T . For simplicity, in the following only currents with compact support are considered.

The **mass** $M(T)$ of a k -current T is the dual norm $M(T) = \sup\{T(\varphi) \mid M(\varphi) \leq 1\}$ of the **comass** $M(\varphi)$ on k -forms, which is defined by $M(\varphi) = \sup\{\|\varphi(x)\| \mid x \in U\}$ with $\|\varphi(x)\| = \sup\{\langle \varphi(x), v_1 \wedge \dots \wedge v_k \rangle \mid v_1, \dots, v_k \text{ are orthonormal vectors at } x \in U\}$. It follows that $M(T)$ coincides with k -dimensional volume when T

is a k -current defined by integration on a k -dimensional simplex. We say that T is **normal** if $M(T)$ and $M(\partial T)$ are finite. Normal currents form a †Banach space with norm $N(T) = M(T) + M(\partial T)$.

A current T is called **rectifiable** if it can be approximated in the mass norm by currents of type $f_*\gamma$, where γ is a finite polyhedral chain with integer coefficients, $f: \text{supp } \gamma \rightarrow U$ is a †Lipshitz mapping of the support of γ into U , and $f_*\gamma$ is the current defined by means of $f_*\gamma(\varphi) = \gamma(f^*\varphi)$. If both T and ∂T are rectifiable, T is called an **integral current**. Integral currents give the appropriate notion of generalized manifolds with boundary in the study of higher-dimensional Plateau problems.

One of the fundamental properties of integral currents is the compactness, stated as follows: Given a compact subset $K \subset U$ and a number $c > 0$, the set of integral currents T such that $\text{supp } T \subset K$ and $N(T) \leq c$ is sequentially compact in the †weak topology. Since the mass $M(T)$ is †lower semicontinuous in the weak topology, it follows that Plateau's problem can always be solved in the space of integral currents (\rightarrow Section C; 334 Plateau's Problem). The question arises: To what extent is this a satisfactory solution to the problem? For codimension 1, it is known from the work of Federer and others that an integral $(n-1)$ -current of least mass in \mathbb{R}^n is nonsingular in codimension < 7 . In particular, in \mathbb{R}^n , $n \leq 7$, every integral $(n-1)$ -current of least mass is an analytic manifold. In general codimensions, it is known that the set of regular points is dense (Reifenberg, Almgren, and others).

The definition of rectifiable and integral currents carries over to those on a Riemannian manifold M in a natural way. Then the space of integral currents $I_*(M)$ on M with the boundary operator ∂ , for which $\partial^2 = 0$, form a chain complex. It is then a fundamental theorem, due to Federer and Fleming, in homological integration theory that there is a natural isomorphism $H_*(I_*(M)) \cong H_*(M; \mathbb{Z})$ of the homology of the complex of integral currents with the integral singular homology groups of M . From this it follows that if M is a compact Riemannian manifold M , then each class $\alpha \in H_p(I_*(M)) \cong H_p(M; \mathbb{Z})$ contains an integral current of least mass among all integral currents in α .

For a homology class of codimension 1, it has also been proved by Almgren that if M is a compact Riemannian manifold of dimension ≤ 7 , then for each $\alpha \in H_{n-1}(M; \mathbb{Z})$ there exists a finite collection of mutually disjoint, compact oriented minimal hypersurfaces S_1, \dots, S_l embedded in M and integers n_1, \dots, n_l such that the integral current $\sum_{j=1}^l n_j S_j$ represents α . On the other hand, it has been recently proved

that every compact Riemannian manifold of dimension ≤ 6 contains a nonempty closed embedded minimal hypersurface (J. T. Pitts).

(2) **Varifolds.** The theory of integral currents developed by Federer, Fleming, and others yields reasonable spaces for purposes of the calculus of variations. However, it is not entirely feasible to use these in the study of the actual soap films that occur in physical experiments. It turns out that we should work in a more set-theoretic fashion and give up the notion of orientability and the boundary operator. A convenient theory for describing these physical experiments is the theory of varifolds developed by Almgren.

A k -dimensional **varifold** on a Riemannian manifold M is a \dagger Radon measure on the bundle $G_k(M)$ of unoriented tangent k -planes of M . For simplicity, only varifolds with compact support are considered. These are regarded as continuous linear functionals on the space $C(G_k(M))$ of continuous functions on $G_k(M)$. Thus a k -dimensional submanifold S of finite volume embedded in M determines a varifold V_S by integration:

$$V_S(f) = \int_S f(T_x S) d\mathcal{H}^k(x), \quad f \in C(G_k(M)),$$

where \mathcal{H}^k denotes the k -dimensional \dagger Hausdorff measure on M . More generally, to any rectifiable current there corresponds an underlying varifold obtained by neglecting orientations.

Let $V_k(M)$ denote the space of k -dimensional varifolds on M . Given a varifold $V \in V_k(M)$, the **mass** $M(V)$ is defined to be the V -measure of the total space, i.e., $M(V) = V(1)$. Let $f: M \rightarrow M$ be a C^1 -mapping. Then f induces naturally a mapping f_* of $V_k(M)$ into itself. In particular, if X is a smooth vector field on M with associated flow f_t , then there is a smooth function $M(t) = M(f_{t*} V)$. A varifold $V \in V_k(M)$ is then called a k -dimensional **minimal variety** in M if the first variation $(d/dt)M(t)|_{t=0} = 0$ for all smooth vector fields on M . For example, minimal submanifolds, complex analytic subvarieties of Kähler manifolds and integral currents of least mass are minimal varieties.

An appropriate notion of rectifiable and integral varifolds is defined, and an analog of the compactness theorem can be obtained. As a consequence, it was proved by Almgren using \dagger Morse theory methods that if M is an n -dimensional compact Riemannian manifold, then for each p , $1 \leq p \leq n-1$, there exists at least one minimal variety of dimension p . As for the regularity of minimal varieties, it is known that if V is a k -dimensional variety, then in the support of V there is a relatively open dense subset that is a regular minimal submanifold of dimension k (W. K. Allard).

H. Maximal Hypersurfaces in Minkowski Space

Let L^{n+1} be a Minkowski space, i.e., $L^{n+1} = \{(x_1, \dots, x_n, t) | (x_1, \dots, x_n) \in \mathbf{R}^n, t \in \mathbf{R}\}$ with the \dagger Lorentzian metric $\sum_{i=1}^n (dx_i)^2 - (dt)^2$. Let M be a \dagger spacelike hypersurface of L^{n+1} so that the induced metric on M is Riemannian. If the mean curvature vector field H of M , defined in the same way as in the Riemannian case, vanishes identically, then M is called **maximal**. In contrast to the Riemannian case, by the variation in the normal direction of H , the volume increases, provided $H \neq 0$. However, the equation describing a maximal hypersurface is similar to that for the Riemannian case (\rightarrow Sections D (1), F (1)). Indeed, let D be a domain in \mathbf{R}^n and $f: D \rightarrow \mathbf{R}$ a smooth function. Then the graph of f in L^{n+1} is a maximal hypersurface if and only if f satisfies the following quasilinear partial differential equation of the second order:

$$(1 - |\nabla f|^2) \sum_{i=1}^n \frac{\partial^2 f}{\partial x_i^2} + \sum_{i,j=1}^n \frac{\partial f}{\partial x_i} \frac{\partial f}{\partial x_j} \frac{\partial^2 f}{\partial x_i \partial x_j} = 0.$$

This is \dagger elliptic for $|\nabla f| < 1$, since M is spacelike. E. Calabi proposed a problem similar to Bernshtein's in 1968. Contrary to Bernshtein's case, the answer is affirmative for any n .

Namely, a maximal hypersurface in L^{n+1} defined as the graph of a function on the entire space \mathbf{R}^n is a hyperplane in \mathbf{R}^{n+1} . More generally, a maximal hypersurface, which is a closed set in L^{n+1} , is a hyperplane (S. Y. Cheng and S. T. Yau). It is also known that any maximal hypersurface in L^{n+1} is stable.

276 (I.6) Model Theory

A. Language

Every mathematical theory has an appropriate language. To determine a language for a theory means to determine a language for the related mathematical system. Such a language consists of the following symbols (the symbols given here are examples of only one notational system).

- (1) Symbols that express logical concepts (*logical symbols): $\forall, \exists, \neg, \wedge, \vee, \rightarrow$;
- (2) *free variables: a_0, a_1, a_2, \dots ;
- (3) *bound variables: x_0, x_1, x_2, \dots ;
- (4) symbols that denote individual objects (individual constants): $c_0, c_1, c_2, \dots, c_\alpha, \dots$;
- (5) *function symbols: $f_0, f_1, f_2, \dots, f_\alpha, \dots$;
- (6) *predicate symbols: $P_0, P_1, P_2, \dots, P_\alpha, \dots$.

The *cardinalities of the sets of symbols in (4), (5), and (6) are arbitrary, except that there must be at least one predicate symbol. It is assumed that each set of symbols is *well ordered. Also, it is understood that to each f_j in (5) there corresponds a positive integer i_j , while to each P_j there corresponds a nonnegative integer (these integers are called the number of arguments of f_j and P_j , respectively).

In practice, other kinds of languages are also dealt with. One example is a system with infinitely long expressions, which permits

*transfinite ordinals for the numbers of arguments of f_j and P_j , and which has the extended concepts $\bigwedge_{\alpha < \beta}, \bigvee_{\alpha < \beta}, \exists x_1 \dots \exists x_\alpha \dots$ for $\alpha < \beta$, and $\forall x_1 \forall x_2 \dots \forall x_\alpha \dots$ for $\alpha < \beta$, where α and β are transfinite ordinals. Another language includes variables of higher *type as well as \forall and \exists over those variables. Free and bound variables may not be distinguished typographically. In that case a variable not bound by \forall or \exists in a *formula is called **free**. (The notion of a formula is defined later.) To simplify this discussion, however, we restrict ourselves to the *first-order predicate language with a typographic distinction between free and bound variables. We also assume that there are only a countable number of variables, and hence we use natural numbers as subscripts.

Set $L_1 = \{\text{logical symbols}\}$, $L_2 = \{a_0, a_1, a_2, \dots\}$, $L_3 = \{x_0, x_1, x_2, \dots\}$, $L_4 = \{c_0, c_1, c_2, \dots\}$, $L_5 = \{f_0, f_1, f_2, \dots\}$, $L_6 = \{P_0, P_1, P_2, \dots\}$, $L = \langle L_1, L_2, L_3, L_4, L_5, L_6 \rangle$. To determine a language L is to specify such a list L . Since $\forall, \exists, \neg, \wedge, \vee, \rightarrow$, are normally used for L_1 , a_0, a_1, a_2, \dots for L_2 , and x_0, x_1, x_2, \dots for L_3 , we may assume that these are fixed, and hence to determine a language is to determine $\langle L_4, L_5, L_6 \rangle$. We take $\langle L_1, L_2, L_3 \rangle$ just described and assume an arbitrary but fixed $L = \langle L_4, L_5, L_6 \rangle$. First we define the notions term of L (or L -term) and formula of L (or L -formula).

Definition of the **terms** of L (L -terms): (1) Each free variable a_j is an L -term. (2) Each individual constant c_j of L is an L -term. (3) If f_j is a function symbol of L , i_j is the number of arguments of f_j , and each of t_1, \dots, t_{i_j} is an L -term, then $f_j(t_1, \dots, t_{i_j})$ is also an L -term. (4) The L -terms are only those constructed by (1)–(3).

A term that does not contain a free variable is called a **closed term**.

Definition of the **formulas** of L (or L -formulas): (1) Let P_j be a predicate symbol of L and i_j be the corresponding natural number. If each of t_1, \dots, t_{i_j} is an L -term, then $P_j(t_1, \dots, t_{i_j})$ is an L -formula. This type of formula is called a **prime formula** (or **atomic formula**). (2) If A and B are L -formulas, then each of $\neg(A)$, $(A) \wedge (B)$, $(A) \vee (B)$, and $(A) \rightarrow (B)$ is an L -formula. (3) Let F be an L -formula and x_i be a bound variable that does not occur in F . Then an expression obtained by putting $(\)$ around F , replacing some occurrences in F of a free variable, say a_j , by x_i , and prefixing $\forall x_i$ or $\exists x_i$ is an L -formula. (4) The L -formulas are only those constructed by (1)–(3).

A formula that has no occurrence of a free variable is called a **closed formula**. The parentheses used in the formation of a formula may be omitted if no ambiguity arises thereby.

B. Structures

Let L be a specific language as described in the previous section. Then $\mathfrak{M} = [M : \rho; \sigma; \tau]$ defined by (1)–(4) below is called a **structure** for L (or L -structure).

(1) M is a nonempty set. (M is called the **universe** of \mathfrak{M} .)

(2) ρ is a mapping from L_4 into M .

(3) Let $L_5^i = \{f_j \mid \text{the number of arguments of } f_j \text{ is } i\}$. Then $L_5 = L_5^1 \cup L_5^2 \cup \dots \cup L_5^i \cup \dots$ provides a partition of L_5 . Let \mathfrak{F}_i be the set of all mappings from $M^i = M \times \dots \times M$ (i times) into M and σ_i be a mapping from L_5^i into \mathfrak{F}_i . We define σ for an arbitrary f of L_5 by $\sigma(f) = \sigma_i(f)$, where i is the number of arguments of f . Then σ is obviously a mapping from L_5 into $\bigcup_{i=1}^{\infty} \mathfrak{F}_i$.

(4) Decompose L_6 into $L_6^0 \cup L_6^1 \cup \dots \cup L_6^i \cup \dots$ as in (3). Let P_i be the set of all subsets of M^i and τ_i be a mapping from L_6^i into P_i , where P_0 is the set $\{M, \emptyset\}$ (\emptyset is the empty set). Then τ is defined for every i and for an arbitrary P of L_6^i by $\tau(P) = \tau_i(P)$.

If we denote $\rho(c)$ by \bar{c} , $\sigma(f)$ by \bar{f} , and $\tau(P)$ by \bar{P} , then we may understand that ρ is represented by $\bar{c}_0, \bar{c}_1, \dots$, σ is represented by $\bar{f}_0, \bar{f}_1, \dots$, and τ is represented by $\bar{P}_0, \bar{P}_1, \dots$. Therefore \mathfrak{M} is normally expressed as

$$\mathfrak{M} = [M : \bar{c}_0, \bar{c}_1, \dots; \bar{f}_0, \bar{f}_1, \dots; \bar{P}_0, \bar{P}_1, \dots].$$

C. Satisfiability

We fix not only a language L but also a structure \mathfrak{M} for L . Then the property that an L -formula is **satisfiable** is defined by the following procedure:

Let m, n, \dots stand for i -sequences of the elements of M , say $(m_0, m_1, \dots), (n_0, n_1, \dots), \dots$, called \mathfrak{M} -sequences. We write $m = n$ to indicate that each entry of m except the i th one is equal to the corresponding entry of n . Using these concepts, the value of an L -term at an \mathfrak{M} -sequence m , denoted by $t[m]$, is defined as follows:

(1) If t is a free variable a_j , then $t[m] = m_j$.

(2) If t is an individual constant c_j , then $t[m] = \bar{c}_j$.

(3) If t is of the form $f_j(t_1, \dots, t_i)$, then $t[m] = \bar{f}_j(t_1[m], \dots, t_i[m])$. If t is an L -term, then evidently $t[m]$ is an element of M .

Based on this definition of $t[m]$, the relation A is satisfiable by m in \mathfrak{M} , denoted by $\mathfrak{M}, m \models A$, is defined for an arbitrary L -formula A and an arbitrary \mathfrak{M} -sequence m as follows:

(1) $\mathfrak{M}, m \models P_j(t_1, \dots, t_i) \Leftrightarrow \langle t_1[m], \dots, t_i[m] \rangle \in \bar{P}_j$.

(2) $\mathfrak{M}, m \models \neg B \Leftrightarrow \mathfrak{M}, m \models B$ is false.

(3) $\mathfrak{M}, m \models B \wedge C \Leftrightarrow \mathfrak{M}, m \models B$ and $\mathfrak{M}, m \models C$.

(4) $\mathfrak{M}, m \models B \vee C \Leftrightarrow \mathfrak{M}, m \models B$ or $\mathfrak{M}, m \models C$.

(5) $\mathfrak{M}, m \models B \rightarrow C \Leftrightarrow \mathfrak{M}, m \models B$ implies $\mathfrak{M}, m \models C$.

(6) $\mathfrak{M}, m \models \forall x_j F(x_j) \Leftrightarrow \mathfrak{M}, n \models F(a_i)$ for an arbitrary n that satisfies $m = n$, where a_i has the least index among the free variables that do not occur in $F(x_j)$.

(7) $\mathfrak{M}, m \models \exists x_j F(x_j) \Leftrightarrow$ there exists an n such that $n = m$ and $\mathfrak{M}, n \models F(a_i)$, where a_i satisfies the same condition as in (6).

Following are some consequences of this definition.

(1) For an arbitrary L -formula A and an arbitrary \mathfrak{M} -sequence m , exactly one of $\mathfrak{M}, m \models A$ and $\mathfrak{M}, m \models \neg A$ holds.

(2) Let a_{j_1}, \dots, a_{j_i} include all free variables that occur in A , and let m and n be \mathfrak{M} -sequences for which $m_{j_1} = n_{j_1}, \dots, m_{j_i} = n_{j_i}$. Then $\mathfrak{M}, m \models A$ and $\mathfrak{M}, n \models A$ are equivalent.

So we may write $\mathfrak{M} \models A \left[\begin{smallmatrix} a_{j_1}, \dots, a_{j_i} \\ m_{j_1}, \dots, m_{j_i} \end{smallmatrix} \right]$ instead of $\mathfrak{M}, m \models A$, for any formula A whose free variables are among a_{j_1}, \dots, a_{j_i} , and any \mathfrak{M} -sequence m .

(3) If A is a closed formula, then for an arbitrary pair of sequences m and n , $\mathfrak{M}, m \models A$ and $\mathfrak{M}, n \models A$ are equivalent. Therefore, for a closed formula A , we may express the statement "for some (or, equivalently, for all) \mathfrak{M} -sequence m , $\mathfrak{M}, m \models A$ holds" by $\mathfrak{M} \models A$.

(4) Let a_i be an arbitrary variable that does not occur in $\forall x F(x)$ or $\exists x F(x)$. Then $\mathfrak{M}, m \models \forall x F(x)$ is equivalent to $\mathfrak{M}, n \models F(a_i)$ for an arbitrary n such that $n = m$. Likewise, $\mathfrak{M}, m \models \exists x F(x)$ is equivalent to the statement that there is an n such that $n = m$ and $\mathfrak{M}, n \models F(a_i)$.

D. Models

Here again we fix a language L . Let A be a closed L -formula and \mathfrak{M} an L -structure. If $\mathfrak{M} \models A$, then \mathfrak{M} is called a **model** of A .

Furthermore, if $\Gamma = \{A_0, A_1, \dots\}$ is an arbitrary set of closed formulas and $\mathfrak{M} \models A_i$ for all A_i in Γ , then the structure \mathfrak{M} is called a **model** of Γ .

(1) **Consistency.** Consider a logical system whose language is L . If there is a model of the set of all provable closed formulas of the system, then the system is i -consistent. In particular, the i -first-ordered predicate calculus is consistent.

(2) **Completeness.** A logical system is said to be **complete** if every closed formula that is satisfied in every structure is provable in the

system. In particular, the first-order predicate calculus is complete.

K. Gödel proved (2). Later L. Henkin gave an alternative proof whose essential idea contributed to proving the following proposition: If a set Γ of closed L -formulas is consistent, then there is a model of Γ . Henkin also introduced a (nonstandard) second-order semantics, relative to which the \dagger second-order predicate calculus is complete. This can be shown by extending Henkin's technique (for the first order) to the second-order language.

(3) Here we extend the language slightly by adding the second-order free predicate variables $\alpha_1^n, \alpha_2^n, \dots, \alpha_i^n, \dots$ ($n = 1, 2, \dots$) and the second-order bound predicate variables $\varphi_1^n, \varphi_2^n, \dots, \varphi_i^n, \dots$ ($n = 1, 2, \dots$), where n indicates the number of arguments of a variable. Otherwise the definition of the language is the same as for the case of the first-order predicate calculus. For simplicity, however, we assume that there are no individual constants, function symbols, or predicate symbols.

The structure is defined as follows: Put $\mathfrak{M} = [M: S_1, S_2, \dots, S_n, \dots]$, where M is a nonempty set and S_n is a set of subsets of $M \times \dots \times M$ (n times). An \mathfrak{M} -sequence m is defined as before, and s_n denotes $(s_1^n, s_2^n, \dots, s_i^n, \dots)$, where each s_i^n is a member of S_n . The concept of satisfiability is defined as follows:

$\mathfrak{M}, (m, s_1, \dots, s_n, \dots) \models \alpha_j^n(x_{i_1}, \dots, x_{i_n}) \Leftrightarrow (m_{i_1}, \dots, m_{i_n}) \in s_j^n$.

$\mathfrak{M}, (m, s_1, \dots, s_n, \dots) \models \forall \varphi_k^n A(\varphi_k^n) \Leftrightarrow$ for an arbitrary s'_n for which $s'_n \neq s_n$, $\mathfrak{M}, (m, s_1, \dots, s'_n, \dots) \models A(\alpha_j^n)$, where α_j^n has the smallest index among the free predicate variables that do not occur in $A(\varphi_k^n)$.

$\mathfrak{M}, (m, s_1, \dots, s_n, \dots) \models \exists \varphi_k^n A(\varphi_k^n) \Leftrightarrow$ there exists an s'_n such that $s'_n \neq s_n$ and $\mathfrak{M}, (m, s_1, \dots, s'_n, \dots) \models A(\alpha_j^n)$, where α_j^n satisfies the same condition as in the previous clause.

Satisfiability for other cases is defined as for first-order predicate language. A structure \mathfrak{M} is called **normal** if all axioms of the second-order predicate calculus are true in \mathfrak{M} .

Completeness of the second-order predicate calculus: Every closed formula that is satisfiable in all normal structures is provable in the second-order predicate calculus.

(4) Let the cardinality of L_4 be τ , and Γ be an arbitrary set of closed L -formulas. If Γ has a model, then Γ has a model of cardinality $\max(\tau, \aleph_0)$. This follows from Henkin's method. Historically, however, it was first proved by Th. Skolem and L. Löwenheim for a special case, and was later generalized by A. I. Mal'tsev and A. Robinson.

(5) The following results are all due to A. Tarski and R. L. Vaught.

Definition 1. Two L -structures \mathfrak{M} and \mathfrak{N} are said to be **elementarily (arithmetically) equivalent** if for an arbitrary closed L -formula A , $\mathfrak{M} \models A \Leftrightarrow \mathfrak{N} \models A$.

Definition 2. Let

$\mathfrak{M} = [M: q_0, q_1, \dots; g_0, g_1, \dots; Q_0, Q_1, \dots]$

and

$\mathfrak{N} = [N: r_0, r_1, \dots; h_0, h_1, \dots; R_0, R_1, \dots]$

be two structures. \mathfrak{M} is an **elementary extension** of \mathfrak{N} if the following two conditions are satisfied: (i) $M \supset N$; $q_j = r_j$ ($j = 0, 1, \dots$); the restriction of g_j to N is identical to h_j ($j = 0, 1, \dots$); the restriction of Q_j to N is identical to R_j ($j = 0, 1, \dots$). (If this condition holds, then \mathfrak{M} is said to be an extension of \mathfrak{N} .) (ii) For an arbitrary L -formula A and an arbitrary \mathfrak{N} -sequence n , if $\mathfrak{N}, n \models A$ then $\mathfrak{M}, n \models A$.

Theorem 1. Let \mathfrak{M} be an extension of \mathfrak{N} . A necessary and sufficient condition for \mathfrak{M} to be an elementary extension of \mathfrak{N} is that for an arbitrary L -formula of the form $\exists x F(x)$ and an arbitrary \mathfrak{N} -sequence n , if $\mathfrak{M}, n \models \exists x F(x)$, then there is some element n of N such that for the \mathfrak{M} -sequence m for which $m \stackrel{i}{=} n$ and $m_i = n$, $\mathfrak{M}, m \models F(a_i)$, where a_i is an arbitrary free variable that does not occur in $F(x)$.

Theorem 2. Here we place a condition on L that each set of symbols be at most countable and arranged in the ω -type (\rightarrow 312 Ordinal Numbers). Let the cardinality of the universe M of \mathfrak{M} be an infinite cardinal α , M' be a subset of M of cardinality ϵ , and b be an infinite cardinal that satisfies $\epsilon \leq b \leq \alpha$. Then there exists an L -structure \mathfrak{N} whose universe N has cardinality b and such that $M' \subset N$ and \mathfrak{M} is an elementary extension of \mathfrak{N} .

Theorem 3. Suppose that L satisfies the same condition as in Theorem 2. Let the cardinality of the universe M of \mathfrak{M} be α (α is an infinite cardinal) and b be a cardinal for which $\alpha \leq b$. Then there exists an L -structure \mathfrak{N} that is a proper elementary extension of \mathfrak{M} and whose universe has cardinality b .

E. Ultraproducts

Assume that for a set of L -structures Σ and a set of indices I , there is a mapping θ from I onto Σ . If α is a member of I , \mathfrak{M} is a member of Σ , and $\theta(\alpha) = \mathfrak{M}$, then \mathfrak{M} may be denoted by \mathfrak{M}^α . It should be noted that there may be more than one α corresponding to the same structure. If D is a \dagger maximal filter of I and \mathfrak{M}^α

is expressed as

$$\mathfrak{M}^\alpha = [M^\alpha, \bar{c}^\alpha, \dots, \bar{f}^\alpha, \dots, \bar{P}^\alpha, \dots],$$

then $\prod_{\alpha \in I} M^\alpha$ is defined by

$$\prod_{\alpha \in I} M^\alpha = \{ \varphi \mid \varphi \text{ is a mapping from } I \text{ into } \bigcup_{\alpha \in I} M^\alpha, \text{ where } \varphi(\alpha) \in M^\alpha \}.$$

For any two elements φ and ψ of $\prod_{\alpha \in I} M^\alpha$, $\varphi \stackrel{D}{=} \psi$ is defined by

$$\varphi \stackrel{D}{=} \psi \Leftrightarrow \{ \alpha \mid \varphi(\alpha) = \psi(\alpha) \} \in D.$$

Then $\varphi \stackrel{D}{=} \psi$ is an equivalence relation between the elements of $\prod_{\alpha \in I} M^\alpha$. Furthermore, the set $\prod_{\alpha \in I} M^\alpha$ partitioned by $\stackrel{D}{=}$ is expressed by $\prod_{\alpha \in I} M^\alpha / D$, and each element m of $\prod_{\alpha \in I} M^\alpha / D$ is expressed by $m = [\varphi]$, where φ is a representing element of m .

Next we define an operator that produces a new structure from Σ . Put $M = \prod_{\alpha \in I} M^\alpha / D$. For an individual constant c of L , let $\bar{c} = [\varphi]$, where $\varphi(\alpha) = c^\alpha$ for every α . For an n -ary function f of L and arbitrary elements $m_1 = [\varphi_1], \dots, m_n = [\varphi_n]$ of M , define $\bar{f}(m_1, \dots, m_n) = [\psi]$, where $\psi(\alpha) = \bar{f}^\alpha(\varphi_1(\alpha), \dots, \varphi_n(\alpha))$ for every α . For an n -ary predicate P of L , define $\langle m_1, \dots, m_n \rangle \in \bar{P}$ by

$$\langle m_1, \dots, m_n \rangle \in \bar{P} \Leftrightarrow \{ \alpha \mid \langle \varphi_1(\alpha), \dots, \varphi_n(\alpha) \rangle \in P^\alpha \} \in D.$$

According to these definitions, put

$$\mathfrak{M} = [M, \bar{c}, \dots, \bar{f}, \dots, \bar{P}, \dots],$$

and denote it by $\prod_{\alpha \in I} \mathfrak{M}^\alpha / D$, called the **ultraproduct** of $\{\mathfrak{M}^\alpha\}_{\alpha \in I}$ (with respect to D). \mathfrak{M} is an L -structure.

Fundamental Theorem of Ultraproducts.

Let $\mathfrak{M} = \prod_{\alpha \in I} \mathfrak{M}^\alpha / D$ be the ultraproduct of $\{\mathfrak{M}^\alpha\}_{\alpha \in I}$, $m = (m_1, m_2, \dots)$ be an \mathfrak{M} -sequence, φ_i be a representing element of m_i , and A be an arbitrary formula. Then $\mathfrak{M}, m \models A \Leftrightarrow \{ \alpha \mid \mathfrak{M}^\alpha, (\varphi_1(\alpha), \varphi_2(\alpha), \dots) \models A \} \in D$.

By using this fundamental theorem we have the following result: Suppose that Γ is a set of closed formulas in L such that every finite subset of Γ has a model. Let I be the set of all the finite subsets of Γ . For each $\alpha \in I$ and each $A \in \Gamma$, let \mathfrak{M}^α be a model of α and \hat{A} the set of all the finite sets in I which contain A as a member. Let $F = \{ \hat{A} \mid A \in \Gamma \}$. Since F has the finite intersection property, there is a maximal filter D such that $D \supseteq F$. Let \mathfrak{M} be the ultraproduct $\prod_{\alpha \in I} \mathfrak{M}^\alpha / D$. Since \hat{A} is a subset of the set $\{ \alpha \mid \mathfrak{M}^\alpha \models A \}$ and \hat{A} belongs to D , the set $\{ \alpha \mid \mathfrak{M}^\alpha \models A \}$ belongs to D , for each $A \in \Gamma$. Hence we have that M is a model of Γ , by the foregoing fundamental theorem of ultra-

products. Therefore, we have the following theorem.

Compactness Theorem. A set Γ of closed formulas has a model if and only if every finite subset of it has a model.

In the case where all the structures \mathfrak{M}^α coincide with the single structure \mathfrak{R} , the ultraproduct of $\{\mathfrak{M}^\alpha\}_{\alpha \in I}$ (with respect to D) may be written \mathfrak{R}^I / D and called the **ultrapower** of \mathfrak{R} (with respect to D).

Let

$$\mathfrak{M} = [M; q_0, q_1, \dots; g_0, g_1, \dots; Q_0, Q_1, \dots]$$

and

$$\mathfrak{N} = [N; r_0, r_1, \dots; h_0, h_1, \dots; R_0, R_1, \dots]$$

be two structures. \mathfrak{M} and \mathfrak{N} are said to be **isomorphic** if there is a bijection f from M to N such that the following three conditions hold: (i) $f(q_0) = r_0, f(q_1) = r_1, \dots$ (ii) The sequences g_0, g_1, \dots and h_0, h_1, \dots are of the same type and $f(g_j(a_1, \dots, a_n)) = h_j(f(a_1), \dots, f(a_n))$ holds for every n -tuple a_1, \dots, a_n in M . (iii) The sequences Q_0, Q_1, \dots and R_0, R_1, \dots are of the same type and $R_j = \{ \langle f(a_1), \dots, f(a_n) \rangle \mid \langle a_1, \dots, a_n \rangle \in Q_j \}$.

Let j be the function from N to N^I / D defined by $j(a) = [\varphi_a]$ for each $a \in N$, where φ_a is the constant function from I to N such that $\varphi_a(\alpha) = a$ for each $\alpha \in I$. Let \mathfrak{M} be the substructure of \mathfrak{N}^I / D whose universe is the range of j . Then j is an isomorphism of \mathfrak{N} to \mathfrak{M} . In the following we identify a and $j(a)$ for each $a \in N$. Then \mathfrak{N} is an elementary substructure of \mathfrak{N}^I / D by the fundamental theorem of ultraproducts.

If \mathfrak{M} and \mathfrak{N} are isomorphic, then \mathfrak{M} and \mathfrak{N} are elementarily equivalent. By using this fact and the fundamental theorem of ultraproducts, we have the following result. Let \mathfrak{M} and \mathfrak{N} be two structures. If there is a nonempty set I and a maximal filter D on I such that \mathfrak{M}^I / D and \mathfrak{N}^I / D are isomorphic, then \mathfrak{M} and \mathfrak{N} are elementarily equivalent. H. J. Keisler proved the converse of this proposition by using the G.C.H. (generalized continuum hypothesis), and later S. Shelah proved it without the G.C.H. **Keisler-Shelah isomorphism theorem:** Let \mathfrak{M} and \mathfrak{N} be two structures. Then \mathfrak{M} and \mathfrak{N} are elementarily equivalent if and only if there is a nonempty set I and a maximal filter D on I such that \mathfrak{M}^I / D and \mathfrak{N}^I / D are isomorphic.

The ultraproduct operation has various applications in number theory, algebraic geometry, and analysis. Here we give an example due to J. Ax and S. Kochen. Let P be the set of prime numbers. Let \mathbb{Q}_p and $\mathbb{Z}_p((t))$ be the field of p -adic numbers and the field of formal

power series over $Z_p = \{0, 1, \dots, p-1\}$ for each p in P , respectively. **Ax-Kochen isomorphism theorem:** Suppose that D is a nonprincipal maximal filter on P . Then $\prod_{p \in P} \mathbf{Q}_p/D$ and $\prod_{p \in P} Z_p((t))/D$ are isomorphic.

As an immediate consequence of this theorem, we have the following partial solution of Artin's conjecture on Diophantine equations.

Theorem: For each positive integer d , there exists a finite set Y of primes such that every homogeneous polynomial $f(t_1, \dots, t_n)$ of degree d over \mathbf{Q}_p , with $n > d^2$, has a nontrivial zero in \mathbf{Q}_p for every $p \notin Y$ (\rightarrow 118 Diophantine Equations).

We give another example in nonstandard analysis. A. Robinson developed the general theory of nonstandard analysis in [10]. Here we explain a theorem due to A. R. Bernstein. Let X be a nonempty set and $U(X)$ be the smallest transitive set (i.e., $a \in b$ and $b \in U(X)$ imply $a \in U(X)$) which has X as a member and is closed under the following operations: pairing, union, power set, and subset operation (i.e., $a \in U(X)$ and $b \subset a$ imply $b \in U(X)$). Let L be the first-order predicate logic with equality whose set of nonlogical constants consists of a binary predicate symbol \in and individual constant symbols c_a for $a \in U(X)$ (\rightarrow 411 Symbolic Logic F). Then the first-order structure $\mathfrak{R} = [U(X); a(a \in U(X)); E]$ is an L -structure, where E is the \in relation on the set $U(X)$. Let $\mathfrak{M} = [U(X)^I/D; a(a \in U(X)); E^I/D]$ be the ultrapower \mathfrak{R}^I/D of \mathfrak{R} with respect to a nonprincipal ultrafilter D on a set I . For each $a \in U(X)$, let a^* be the set of all elements $[\varphi]$ in $U(X)^I/D$ such that $\{i \in I \mid \varphi(i) \in a\} \in D$. Then a is a proper subset of a^* if a is infinite. Since \mathfrak{R} and \mathfrak{M} are elementarily equivalent, these two sets a and a^* have common first-order properties in the following sense: for each formula $\Phi(a_0)$ in L ,

$$(\forall b \in a)(\mathfrak{R} \models \Phi[b^a]) \Leftrightarrow (\forall b \in a^*)(\mathfrak{M} \models \Phi[b^{a_0}]).$$

From this it follows that if r is a relation on a set a in \mathfrak{R} , then r^* is a relation on the set a^* ; and if f is a mapping from a to b in \mathfrak{R} , then f^* is a mapping from a^* to b^* . Hence a^* is a mathematical object which greatly resembles a . By using this type of resemblance between a and a^* we have the following result.

Let H be a Hilbert space over the complex number field \mathbf{C} such that $\dim(H) = \omega$ and let T be a bounded linear operator on H . Let $X = H \cup \mathbf{C}$ and consider the first-order structure \mathfrak{M} as above. Since \mathbf{R} (the set of all real numbers) and \mathbf{N} (the set of all natural numbers) are infinite sets which belong to $U(X)$, \mathbf{R}^* and \mathbf{N}^* have elements which do not belong to \mathbf{R} and \mathbf{N} , respectively. Such elements are called **nonstandard real numbers** and **nonstandard natural numbers**, respectively. By the fundamental

theorem of ultraproducts we can conclude that there are many nonstandard real numbers α such that $0 < {}^*\alpha < {}^*a$ in \mathbf{R}^* for any $a \in \mathbf{R}$. Such a nonstandard real number α is called an **infinitesimal real number**. Since the norm operator $\| \cdot \|$ is a mapping from H to \mathbf{R} , $\| \cdot \|$ is a mapping from H^* to \mathbf{R}^* . If $\|x\|$ ($x \in H^*$) is infinitesimal, then x is said to be **infinitesimal** in H^* . Let S be the set of all linear subspaces of H . For a linear subspace K of H^* that is contained in S^* let K° be the set of elements $x \in H$ such that $x - x_0$ is infinitesimal for some x_0 in K . Then K° is a closed linear subspace of H . Let $e = \{e_i\}_{i \in \mathbf{N}}$ be an orthonormal basis of the Hilbert space H ; e can be considered as a mapping from \mathbf{N} to H , and hence $e^* = \{e_j\}_{j \in \mathbf{N}^*}$ is a mapping from \mathbf{N}^* to H^* . For each $j \in \mathbf{N}^*$, let H_j be the linear subspace of H^* spanned by $\{e_k \mid k \leq j\}$. For a given bounded linear operator T on H , T^* is a linear operator on H^* . We define $T_j = P_j T^* P_j$, where P_j is the projection from H^* to H_j . Since $\dim(H_j) = j$ is a (nonstandard) natural number, there exists a tower $J_{0j} \subset J_{1j} \subset \dots \subset J_{jj} = H_j$ of closed, T_j -invariant linear subspaces of H_j such that $\dim(J_{kj}) = k$ ($k \leq j$). Then J_{kj}° is a closed, T -invariant linear subspace of H . If there is a polynomial $p(x)$ such that $p(T)$ is a compact operator, then we get a nonstandard natural number j such that J_{kj}° is a proper subspace of H for some $k \leq j$. This gives the following result, which is an affirmative solution of a problem of K. Smith and P. R. Halmos.

Theorem (Bernstein [4]): Let T be a bounded linear operator on an infinite-dimensional Hilbert space H over the complex numbers and let $p(x) \neq 0$ be a polynomial with complex coefficients such that $p(T)$ is compact. Then T leaves invariant at least one closed linear subspace of H other than H or $\{0\}$.

F. Categoricity in Powers

Let Γ be a set of closed formulas in a first-order language L which has a designated binary predicate symbol P_0 . In the following, we assume that the interpretation \bar{P}_0 of P_0 by \mathfrak{M} is the equality relation on the universe of \mathfrak{M} for every L -structure \mathfrak{M} . Γ is said to be **categorical** if all the models of Γ are isomorphic. By Theorem 3 in Section D, any Γ having a model of infinite cardinality is not categorical. Hence, there exists no interesting Γ which is categorical. Therefore, we consider the weaker notion of **categoricity in powers**. Let κ be an infinite cardinal and $n(\Gamma, \kappa)$ be the number of nonisomorphic models of Γ of cardinality κ . Then Γ is said to be categorical in κ if $n(\Gamma, \kappa) = 1$, i.e., if all the models of Γ of cardinality κ are isomorphic. There exist many

interesting Γ 's which are categorical in κ for some κ . For example, the set of axioms of algebraically closed fields of characteristic 0 is categorical in \aleph_1 , and the set of axioms of dense linear orderings without endpoints is categorical in \aleph_0 . With respect to this notion, J. Łoś conjectured that if Γ is categorical in κ for some $\kappa > \bar{L}$ (the cardinality of L), then Γ is categorical in κ for all $\kappa > \bar{L}$. This conjecture was solved affirmatively by M. Morley in the case $\bar{L} = \aleph_0$, and later by S. Shelah in the general case. **Theorem (1):** Let Γ be a set of closed formulas in L . Then Γ is categorical in κ for some $\kappa > \bar{L}$ if and only if Γ is categorical in κ for all $\kappa > L$. We also have the following interesting theorem, due to J. T. Baldwin and A. H. Lachlan. **Theorem (2):** Let Γ be a set of closed formulas in L such that $L = \aleph_0$. If Γ is categorical in \aleph_1 , then $n(\Gamma, \aleph_0) = 1$ or \aleph_0 .

As for $n(\Gamma, \kappa)$ there are two famous conjectures due to R. Vaught and others. A set Γ of closed formulas in L is called **complete** in L if it has a model and, for any closed formula A in L , either $A \in \Gamma$ or $\neg A \in \Gamma$.

Conjecture 1. There is no complete set Γ of closed formulas in L such that $\aleph_0 < n(\Gamma, \aleph_0) < 2^{\aleph_0}$.

Conjecture 2. There is no finite set Γ of closed formulas in L such that $n(\Gamma, \aleph_0) = \aleph_0$ and $n(\Gamma, \aleph_1) = 1$.

G. Omitting Type Theorem

By a_0 -formulas (or a -formulas), we mean formulas which have no free variables except a_0 . Suppose that \mathfrak{M} is an L -structure and Σ is a set of a -formulas in L . Then, \mathfrak{M} realizes Σ if there is an element m of the universe of \mathfrak{M} such that $\mathfrak{M} \models A[m]$ for all A in Σ , and \mathfrak{M} omits Σ if \mathfrak{M} does not realize Σ . For example, if L is a first-order language such that $L_4 = \{c_0, c_1\}$, $L_5 = \{f_0, f_1\}$, $L_6 = \{P_0, P_1\}$, where f_0, f_1, P_0, P_1 are all binary, and \mathfrak{M} is the L -structure $[\mathfrak{M}; 0, 1; +, x; =, <]$, where \mathfrak{M} is the set of natural numbers, and $\Sigma = \{P_1(\bar{n}, a) \mid n=0, 1, 2, \dots\}$, where $\bar{0} = c_0$, $\bar{1} = f_0(\bar{0}, c_1)$, \dots , $\bar{n+1} = f_0(\bar{n}, c_1)$, \dots , then clearly \mathfrak{M} omits Σ . Also, if \mathfrak{M} is an L -structure, m is an element of the universe of \mathfrak{M} , and $\Sigma_m = \{A \mid A \text{ is an } a\text{-formula such that } \mathfrak{M} \models A[m]\}$, then clearly \mathfrak{M} realizes Σ_m , where Σ_m is called the type of m in \mathfrak{M} . Suppose that Γ is a set of closed formulas in L . Then, by the completeness theorem of L , we can easily see that Γ has a model realizing Σ if and only if $\Gamma \cup \Sigma$ is consistent. On the other hand, it is rather difficult to obtain a necessary and sufficient condition for Γ to have a model omitting Σ . The following is a sufficient con-

dition: Γ is said to locally omit Σ if there is no a -formula A such that $\Gamma \cup \{A\}$ is consistent and, for any formula B in Σ , $\Gamma \cup \{A, \neg B\}$ is not consistent.

Theorem. Suppose that Γ is a consistent set of closed formulas in a countable language L , and Σ is a set of a_0 -formulas in L . If Γ locally omits Σ , then Γ has a countable model which omits Σ . Also, if Γ has a model of power greater than \beth_ξ omitting Σ for each $\xi < \omega_1$, then Γ has a model omitting Σ in each infinite power, where \beth_ξ is defined by $\beth_0 = \aleph_0$, $\beth_{\xi+1} = 2^{\beth_\xi}$, $\beth_\sigma = \sup_{\xi < \sigma} \beth_\xi$ if σ is a limit ordinal.

277 (III.23) Modules

A. General Remarks

In this article, we consider mainly modules with operator domain (Section C), in particular modules over a \dagger ring. Modules over a

field are linear spaces (\rightarrow 256 Linear Spaces). Modules over a commutative ring are important in algebraic geometry (\rightarrow 16 Algebraic Varieties, 67 Commutative Rings, 284 Noetherian Rings). The theory of modules over a \dagger group ring can be identified with the theory of linear representations of a group (\rightarrow 362 Representations). Modules without operator domain may be regarded as modules over the ring \mathbf{Z} of rational integers, and the theory of finitely generated Abelian groups can be generalized to the theory of modules over a \dagger principal ideal domain (\rightarrow 52 Categories and Functors, 200 Homological Algebra).

B. Modules

A **module** (without operator domain) is a \dagger commutative group M whose law of composition is written additively: $a + b = b + a$ ($a, b \in M$); the \dagger identity element is denoted by 0, and the inverse element of a by $-a$. Every subgroup H of M is a normal subgroup. For any $a \in M$, the left and right cosets of H containing the element a are identical: $H + a = a + H$ (\rightarrow 190 Groups A).

In the set N^M of all mappings of a set M to a module N , we define an addition by the sums of values: $(f + g)(x) = f(x) + g(x)$. Then N^M forms a module. The set $\text{Hom}(M, N)$ of all homomorphisms of a module M to a module N forms a subgroup of the module N^M , called the **module of homomorphisms** of M to N . The composite of homomorphisms is a homomorphism. Hence the set $\text{Hom}(M, M) = \mathcal{E}(M)$ of all endomorphisms of M forms a \dagger ring with respect to the addition and the multiplication defined by composition; this is called the **endomorphism ring** of M . The \dagger unity element of $\mathcal{E}(M)$ is the identity mapping of M , and the \dagger invertible elements of $\mathcal{E}(M)$ are the automorphisms of M .

Let $\{x_\lambda\}_{\lambda \in \Lambda}$ be a family of elements in a module M . The sum $\sum_{\lambda \in \Lambda} x_\lambda$ is well defined if $x_\lambda = 0$ ($\lambda \in \Lambda$) except for a finite number of λ . For any family $\{N_\lambda\}_{\lambda \in \Lambda}$ of subsets of M , $\sum_{\lambda \in \Lambda} N_\lambda$ denotes the set of all elements of the form $\sum_{\lambda \in \Lambda} x_\lambda$ ($x_\lambda \in N_\lambda$), where $x_\lambda = 0$ except for a finite number of λ . If all the N_λ are subgroups of M , then $N = \sum_{\lambda \in \Lambda} N_\lambda$ is also a subgroup, called the **sum** of $\{N_\lambda\}_{\lambda \in \Lambda}$. If every element of N can be written uniquely in the form $\sum_{\lambda \in \Lambda} x_\lambda$ ($x_\lambda \in N_\lambda$), N is called the **direct sum** of $\{N_\lambda\}_{\lambda \in \Lambda}$. When the N_λ are subgroups, this is equivalent to the condition that $N_\lambda \cap \sum_{\lambda \neq \mu \in \Lambda} N_\mu = \{0\}$ ($\lambda \in \Lambda$).

C. Modules with Operator Domain

Suppose that we are given a set A and a module M . If with each pair of elements $a \in A$

and $x \in M$ there is associated a unique element $ax \in M$ satisfying the condition (1) $a(x + y) = ax + ay$ ($a \in A$; $x, y \in M$), we say that A is an **operator domain** of M and M is a **module with operator domain A** (**module over A** or **A -module**) (\rightarrow 190 Groups E). The mapping $A \times M \rightarrow M$ given by $(a, x) \rightarrow ax$ is called the **\dagger operation** of A on M . Any $a \in A$ induces an endomorphism $a_M: x \rightarrow ax$ of M as a module (not as an A -module). To give the structure of an A -module to a module M amounts to giving a mapping $A \rightarrow \mathcal{E}(M)$ ($a \rightarrow a_M$).

If N is a subgroup of an A -module M such that $ax \in N$ for any $a \in A$ and $x \in N$, then N forms an A -module, called an **A -submodule** (or **allowed submodule**) of M . If $\{N_\lambda\}_{\lambda \in \Lambda}$ is a family of A -submodules of an A -module M , then the intersection $\bigcap_{\lambda \in \Lambda} N_\lambda$ and the sum $\sum_{\lambda \in \Lambda} N_\lambda$ are both A -submodules of M .

Let R be an \dagger equivalence relation in an A -module M such that if $a \in A$ and xRy , then $axRay$. Then R is said to be **compatible with the operation** of A . In this case, an operation of A is induced on the quotient set M/R . Moreover, if R is compatible with the addition, namely, xRx' and yRy' imply $(x + y)R(x' + y')$, then M/R forms an A -module, called a **factor A -module** of M . The equivalence class N containing 0 is an A -submodule of M , and M/R coincides with M/N .

D. Modules over a Group or a Ring

If a (multiplicative) group structure is given to the operator domain A of a module M , we always assume (in addition to condition (1) in Section C) that the following two conditions are satisfied: (2) $(ab)x = a(bx)$; (3) $1x = x$ ($a, b \in A$, $x \in M$).

If a ring structure is given to A , we always assume (besides conditions (1) and (2)) that the following condition holds: (4) $(a + b)x = ax + bx$ ($a, b \in A$, $x \in M$). This means that the mapping $A \rightarrow \mathcal{E}(M)$ ($a \rightarrow a_M$) is a \dagger ring homomorphism. If the ring A has unity element 1, and $1_M = \text{identity mapping}$ (namely, condition (3) holds), then the A -module M is called **unitary**. We consider only unitary A -modules. Any module M can be regarded as a \mathbf{Z} -module or as an $\mathcal{E}(M)$ -module.

When M is a module over a ring A , an element of A is called a **scalar**, A itself is called the **ring of scalars** (**basic ring** or **ground ring**), and the operation $A \times M \rightarrow M$ is called the **scalar multiplication**. The elements ax ($a \in A$) are called **scalar multiples** of x , and the totality of these elements is denoted by Ax . Let $\{x_\lambda\}_{\lambda \in \Lambda}$ be a family of elements in M . An element of the form $\sum_{\lambda \in \Lambda} a_\lambda x_\lambda$, where the a_λ are elements of A and equal to 0 except for a finite number

of λ , is called a linear combination of $\{x_\lambda\}_{\lambda \in \Lambda}$. The set N of linear combinations of $\{x_\lambda\}_{\lambda \in \Lambda}$ is the smallest A -submodule of M containing all the x_λ ($\lambda \in \Lambda$) and is equal to the sum $\sum_{\lambda \in \Lambda} Ax_\lambda$. The A -module N is said to be **generated** by $\{x_\lambda\}_{\lambda \in \Lambda}$, and $\{x_\lambda\}_{\lambda \in \Lambda}$ is called a **system of generators** of N . A module having a finite number of generators is said to be **finitely generated** (of **finite type** or simply **finite**). The module Ax generated by a single element x is called **monomial**. If A is a * field (which may be noncommutative), an A -module is a linear space over A (\rightarrow 256 Linear Spaces).

Let a be an element of an A -module M . If there exists a nonzero divisor λ of A such that $\lambda a = 0$, then a is called a **torsion element** of M . We say M is a **torsion A -module** if every element of M is a torsion element, and M is **torsion free** if M has no torsion element other than 0. An element a of M is called **divisible** if for any nonzero divisor $\lambda \in A$ there exists an element $b \in M$ such that $a = \lambda b$. M is called a **divisible A -module** if every element of M is divisible.

Strictly speaking, the A -modules we have considered so far are called **left A -modules**. If we define the operation of A on M by xa ($a \in A, x \in M$) instead of ax and modify conditions (1)–(4) appropriately (in particular, condition (2) becomes $x(ab) = (xa)b$), then M is called a **right A -module**. If A° is a group or ring anti-isomorphic to A , then a left A -module can be naturally identified with a right A° -module. If A is a commutative group or ring, we can disregard the distinction between left and right A -modules.

Let A and B be groups or rings. Sometimes we consider an A -module structure and a B -module structure simultaneously on the same module M . If the operations of A and B commute with each other, namely, $a(bx) = b(ax)$ ($a \in A, b \in B, x \in M$), it is convenient to put one of the operations to the right. If M has a left A -module structure and a right B -module structure, satisfying condition (5) $(ax)b = a(xb)$, then M is called an **A - B -bimodule**. If G is a group and K is a commutative ring, the G - K -bimodule structure is equivalent to the left $K[G]$ -module structure, where $K[G]$ is the * group ring.

E. Operator Homomorphisms

A homomorphism $f: M \rightarrow N$ of A -modules M and N such that $f(ax) = af(x)$ ($a \in A, x \in M$) is called an **A -homomorphism (operator homomorphism or allowed homomorphism)**. If A is a ring, f is also called an **A -linear mapping**. Regarding A as an A -module, an A -linear mapping $M \rightarrow A$ is called a **linear form** on M .

The composite of A -homomorphisms is an A -homomorphism.

Let $f: M \rightarrow L$ be an A -homomorphism of A -modules. The A -submodule $\text{Im } f = f(M)$ of L is called the **image** of f , and the A -submodule $\text{Ker } f = \{x \in M, f(x) = 0\}$ of M is called the **kernel** of f . $\text{Coim } f = M/\text{Ker } f$ is called the **co-image** of f , and $\text{Coker } f = L/\text{Im } f$ the **cokernel** of f . The binary relation xRy on M defined by $f(x) = f(y)$ ($x, y \in M$) coincides with the equivalence relation defined by $x - y \in N = \text{Ker } f$ ($x, y \in M$), and the mapping f induces an A -isomorphism $\bar{f}: M/N \rightarrow f(M)$.

A sequence of A -homomorphisms of A -modules M_n ($n \in \mathbb{Z}$)

$$\dots \rightarrow M_{n-1} \xrightarrow{f_{n-1}} M_n \xrightarrow{f_n} M_{n+1} \rightarrow \dots$$

is called an **exact sequence** if $\text{Im } f_{n-1} = \text{Ker } f_n$ for all n . The A -module $\{0\}$ is denoted by 0. Exactness of $0 \rightarrow N \xrightarrow{f} M$ or $M \xrightarrow{g} L \rightarrow 0$ means that the mapping $f: N \rightarrow M$ is injective or the mapping $g: M \rightarrow L$ is surjective, respectively. In an * inductive (* projective) system $\{M_\lambda, f_{\lambda\mu}\}$ of A -modules, where every $f_{\lambda\mu}: M_\lambda \rightarrow M_\mu$ ($\lambda < \mu$) ($\lambda > \mu$) is an A -homomorphism, the limit $M = \varinjlim M_\lambda$ ($\varprojlim M_\lambda$) is also an A -module. If $0 \rightarrow L_\lambda \rightarrow M_\lambda \rightarrow N_\lambda \rightarrow 0$ is exact for every λ and

$$\begin{array}{ccccc} L_\lambda & \rightarrow & M_\lambda & \rightarrow & N_\lambda \\ \downarrow & & \downarrow & & \downarrow \\ L_\mu & \rightarrow & M_\mu & \rightarrow & N_\mu \end{array}$$

is a * commutative diagram, then $0 \rightarrow \varinjlim L_\lambda \rightarrow \varinjlim M_\lambda \rightarrow \varinjlim N_\lambda \rightarrow 0$ is also exact. For the projective limit, however, we can only state the exactness of $0 \rightarrow \varprojlim L_\lambda \rightarrow \varprojlim M_\lambda \rightarrow \varprojlim N_\lambda$.

The set of all A -homomorphisms of an A -module M to an A -module N , denoted by $\text{Hom}_A(M, N)$, is a subgroup of the module $\text{Hom}(M, N)$, and is called the **module of A -homomorphisms**. The set $\text{Hom}_A(M, M) = \mathcal{E}_A(M)$ of all A -endomorphisms of an A -module M forms a * subring of the ring $\mathcal{E}(M)$ and coincides with the set of all elements commuting with any a_M ($a \in A$). We denote by $GL(M)$ the group of all * invertible elements in $\mathcal{E}_A(M)$. If A is a commutative ring, $\text{Hom}_A(M, N)$ can be regarded as an A -module by defining $(af)(x) = af(x)$, namely, $af = a_M \circ f$. In particular, $\mathcal{E}_A(M)$ is an * associative algebra over A . If M is an A - B -bimodule, $\text{Hom}_A(M, N)$ forms a left B -module by $(bf)(x) = f(xb)$. If N is an A - B -bimodule, $\text{Hom}_A(M, N)$ forms a right B -module by $(fb)(x) = f(x)b$.

F. Direct Products and Direct Sums

In the Cartesian product $P = \prod_{\lambda \in \Lambda} M_\lambda$ of a family $\{M_\lambda\}_{\lambda \in \Lambda}$ of A -modules, we define addition and an A -operation as follows: $\{x_\lambda\} + \{y_\lambda\} = \{x_\lambda + y_\lambda\}$, $a\{x_\lambda\} = \{ax_\lambda\}$. Then P forms

an A -module. We call $\prod_{\lambda \in \Lambda} M_\lambda$ the **direct product** of modules $\{M_\lambda\}_{\lambda \in \Lambda}$. The **canonical projection** assigning x_λ to $\{x_\lambda\}$ is denoted by $p_\lambda: P \rightarrow M_\lambda$. Suppose that an A -module M and A -homomorphisms $f_\lambda: M \rightarrow M_\lambda (\lambda \in \Lambda)$ are given. Then there exists a unique A -homomorphism $f: M \rightarrow P$ such that $p_\lambda \circ f = f_\lambda (\lambda \in \Lambda)$; f is given by $f(x) = \{f_\lambda(x)\}$.

In the direct product $\prod_{\lambda \in \Lambda} M_\lambda$, the set S of all elements whose components x_λ are equal to 0 except for a finite number of λ is called the **direct sum** of modules $\{M_\lambda\}_{\lambda \in \Lambda}$ and is denoted by $\sum_{\lambda \in \Lambda} M_\lambda$ (or $\coprod_{\lambda \in \Lambda} M_\lambda$ or $\bigoplus_{\lambda \in \Lambda} M_\lambda$). The **canonical injection** assigning $\{\dots, 0, x_\lambda, 0, \dots\} \in S$ to $x_\lambda \in M_\lambda$ is denoted by $j_\lambda: M_\lambda \rightarrow S$. If an A -module M and A -homomorphisms $f_\lambda: M_\lambda \rightarrow M$ are given, then there exists a unique A -homomorphism $f: S \rightarrow M$ such that $f \circ j_\lambda = f_\lambda (\lambda \in \Lambda)$, defined by $f(\{x_\lambda\}) = \sum_{\lambda \in \Lambda} f_\lambda(x_\lambda)$. When M is an A -module and $\{N_\lambda\}_{\lambda \in \Lambda}$ is a family of A -submodules of M , the A -homomorphism $f: \sum_{\lambda \in \Lambda} N_\lambda \rightarrow M$ defined by $f(\{x_\lambda\}) = \sum_{\lambda \in \Lambda} x_\lambda$ is an A -isomorphism if and only if M is the direct sum of $\{N_\lambda\}$.

If $M_\lambda = M$ for all $\lambda \in \Lambda$, $\prod_{\lambda \in \Lambda} M_\lambda$ and $\sum_{\lambda \in \Lambda} M_\lambda$ are denoted by M^Λ and $M^{(\Lambda)}$, respectively. M^Λ can be regarded as the set of all mappings of Λ to M . The direct product $M_1 \times \dots \times M_n$ and direct sum $M_1 \oplus \dots \oplus M_n$ of a finite number of A -modules M_1, \dots, M_n , can be identified with each other and, if $M_i = M (1 \leq i \leq n)$, we simply denote it by M^n .

G. Free Modules

Let A be a ring. A family $\{x_\lambda\}_{\lambda \in \Lambda}$ of elements in an A -module M is called **linearly independent** if $\sum_{\lambda \in \Lambda} a_\lambda x_\lambda = 0 (a_\lambda \in A)$ implies $a_\lambda = 0$ for all $\lambda \in \Lambda$. This is equivalent to saying that the mapping $A^{(\Lambda)} \rightarrow M$ that assigns $\sum_{\lambda \in \Lambda} a_\lambda x_\lambda \in M$ to $\{a_\lambda\}$ is injective. A linearly independent family $\{x_\lambda\}_{\lambda \in \Lambda}$ generating M is called a **basis** of M . A family $\{x_\lambda\}_{\lambda \in \Lambda}$ is a basis if and only if every element of M can be written uniquely in the form $\sum_{\lambda \in \Lambda} a_\lambda x_\lambda (a_\lambda \in A)$.

An A -module that has a basis is called a **free module** over A . If A is a field (which may be noncommutative), every A -module is a free module (\rightarrow 256 Linear Spaces). The \dagger cardinality of a basis of a free module M over A depends only on M if A is a field (which may be noncommutative) or a commutative ring; this number is called the **rank** (or **dimension**) of M . Any submodule of a free module over a \dagger principal ideal domain is a free module.

H. Simple Modules and Semisimple Modules

An A -module M is called **simple** if $M \neq 0$ and M has no A -submodules except M and 0.

If M and N are simple A -modules, any A -homomorphism of M to N is an isomorphism or the **zero homomorphism** (i.e., one which sends every element of M to 0) (**Schur's lemma**). If an A -module M is the sum of a family $\{M_\lambda\}_{\lambda \in \Lambda}$ of simple submodules, M is the direct sum of a suitable subfamily $\{M_{\lambda'}\}_{\lambda' \in \Lambda'}$ ($\Lambda' \subset \Lambda$). In this case, M is called **semisimple** (or **completely reducible**).

If an A -module M can be decomposed into the direct sum of A -submodules N and N' , then N' is called a **complementary submodule** of N . An A -module M is semisimple if and only if every A -submodule of M has a complementary submodule. Let A be a ring. Then the A -module A is semisimple if and only if every A -module is semisimple. In this case A is called a \dagger semisimple ring (\rightarrow 368 Rings G). Every simple module over a semisimple ring A is A -isomorphic to a \dagger minimal left ideal of A .

I. Chain Conditions

The set of all A -submodules of an A -module M forms an \dagger ordered set under the inclusion relation. An A -module is called a **Noetherian module** if the ordered set satisfies the \dagger maximal condition and an **Artinian module** if it satisfies the \dagger minimal condition (\rightarrow 311 Ordering C).

Let N be an A -submodule of an A -module M . Then M is Noetherian (Artinian) if and only if N and M/N are both Noetherian (Artinian). A ring A is called a \dagger left Noetherian ring (\dagger left Artinian ring) if A is Noetherian (Artinian) as a left A -module, and similarly for right Noetherian and Artinian rings. Every finitely generated module over a Noetherian (Artinian) ring is Noetherian (Artinian). Over an arbitrary ring A , a module M is Noetherian if and only if every A -submodule of M is finitely generated.

A finite sequence $\{M_i\}_{0 \leq i \leq r}$ of A -submodules of an A -module M is called a \dagger Jordan-Hölder sequence if $M = M_0, M_i \supset M_{i+1}, M_r = \{0\}$, and the $M_i/M_{i+1} (0 \leq i < r)$ are simple. If such a sequence exists, M is said to be of **finite length**. The number r , called the **length** of M , depends only on M . The quotient modules $M_i/M_{i+1} (0 \leq i < r)$ are uniquely determined by M up to A -isomorphism and permutation of the indices (C. Jordan and O. Hölder). An A -module M is of finite length if and only if M is Noetherian and Artinian. A semisimple A -module is of finite length if and only if it is finitely generated.

An A -module M is called **indecomposable** if M cannot be decomposed into the direct sum of two A -submodules different from M and $\{0\}$. Any A -module of finite length can be decomposed into the direct sum of a finite

sequence N_1, \dots, N_n of indecomposable A -submodules different from $\{0\}$. The direct summands N_i ($1 \leq i \leq n$) are unique up to A -isomorphism and permutation of the indices (W. Krull, R. Remak, and O. Schmidt).

J. Tensor Products

Let A be a ring. Given a right A -module M and a left A -module N , we construct a module $M \otimes_A N$ (called the **tensor product** of M and N) and a canonical mapping $\varphi: M \times N \rightarrow M \otimes_A N$ as follows. Let F be a free \mathbb{Z} -module (free Abelian additive group) generated by $M \times N$, and R be the subgroup generated by the elements of the forms $(x + x', y) - (x, y) - (x', y)$, $(x, y + y') - (x, y) - (x, y')$, $(xa, y) - (x, ay)$ ($x, x' \in M, y, y' \in N, a \in A$). We define $M \otimes_A N = F/R$, and call the natural projection φ . If we denote $\varphi(x, y)$ by $x \otimes y$, then we have $(x_1 + x_2) \otimes y = x_1 \otimes y + x_2 \otimes y$, $x \otimes (y_1 + y_2) = x \otimes y_1 + x \otimes y_2$, and $(xa) \otimes y = x \otimes (ay)$. Any element of $M \otimes_A N$ is written in the form $\sum x_i \otimes y_i$ ($x_i \in M, y_i \in N$).

The tensor product $M \otimes_A N$ of M and N and the canonical mapping $\varphi: M \times N \rightarrow M \otimes_A N$ can be characterized as follows: For a module L , a mapping $f: M \times N \rightarrow L$ is called **biadditive** if the conditions $f(x + x', y) = f(x, y) + f(x', y)$, $f(x, y + y') = f(x, y) + f(x, y')$ hold. A biadditive mapping f satisfying the condition $f(xa, y) = f(x, ay)$ is called an **A -balanced mapping**. Then we have (i) the canonical mapping $\varphi: M \times N \rightarrow M \otimes_A N$ is A -balanced; and (ii) for any module L and any A -balanced mapping $f: M \times N \rightarrow L$, there exists a unique homomorphism $f_*: M \otimes_A N \rightarrow L$ such that $f(x, y) = f_*(x \otimes y)$ ($x \in M, y \in N$).

A right (left) A -module can be regarded as a left (right) A° -module, where A° is the ring anti-isomorphic to A . In this sense, we have $M \otimes_A N \cong N \otimes_{A^\circ} M$.

Let A be a commutative ring. For A -modules M, N , and L , a mapping $f: M \times N \rightarrow L$ is called a **bilinear mapping** if f is biadditive and satisfies $f(ax, y) = f(x, ay) = af(x, y)$ ($a \in A, x \in M, y \in N$). The set $\mathfrak{B}(M, N; L)$ of all bilinear mappings $M \times N \rightarrow L$ forms A -submodule of the A -module $L^{M \times N}$. A bilinear mapping $M \times N \rightarrow A$ is called a **bilinear form** on $M \times N$. The tensor product $M \otimes_A N$ becomes an A -module if we define $a(x \otimes y) = (ax) \otimes y (= x \otimes (ay))$, and the canonical mapping $M \times N \rightarrow M \otimes_A N$ is bilinear. For any A -module L and bilinear mapping $f: M \times N \rightarrow L$, there exists a unique A -linear mapping $f_*: M \otimes_A N \rightarrow L$ satisfying $f(x, y) = f_*(x \otimes y)$. By this correspondence $f \leftrightarrow f_*$, we get an A -isomorphism $\mathfrak{B}(M, N; L) \cong \text{Hom}_A(M \otimes_A N, L)$. If A is a field, $M \otimes_A N$ coincides with the ten-

sor product $M \otimes N$ as a linear space (\rightarrow 256 Linear Spaces H, I).

In general, let M be a B - A -bimodule and N be a left A -module. Then $M \otimes_A N$ becomes a left B -module if we define $b(x \otimes y) = (bx) \otimes y$. Let N be an A - B -bimodule and M be a right A -module. Then $M \otimes_A N$ becomes a right B -module if we define $(x \otimes y)b = x \otimes (yb)$. In particular, we have $A \otimes_A N \cong N$, $M \otimes_A A \cong M$.

Let M, M' be right A -modules and N, N' be left A -modules. For A -homomorphisms $f: M \rightarrow M'$ and $g: N \rightarrow N'$, there exists a unique homomorphism $h: M \otimes_A N \rightarrow M' \otimes_A N'$ satisfying $h(x \otimes y) = f(x) \otimes g(y)$; h is called the **tensor product** of f, g and is denoted by $f \otimes g$. We give here some simple examples (also \rightarrow Section L).

Examples. (1) Let M, N be free modules (linear spaces, for example) over a commutative ring A . If $\{x_i\}_{i \in I}$ and $\{y_j\}_{j \in J}$ are bases of M and N , respectively, $M \otimes_A N$ is also a free module with a basis $\{x_i \otimes y_j\}_{i \in I, j \in J}$. If the dimensions $\dim M, \dim N$ are finite, $\dim M \otimes_A N = \dim M \dim N$.

(2) For an \mathfrak{a} -ideal of a commutative ring A , the \mathfrak{a} -factor ring $M = A/\mathfrak{a}$ can be regarded as an A -module, and we have $M \otimes_A N \cong N/\mathfrak{a}N$. For instance, $(\mathbb{Z}/m\mathbb{Z}) \otimes_{\mathbb{Z}} (\mathbb{Z}/n\mathbb{Z}) \cong \mathbb{Z}/(m, n)\mathbb{Z}$, where (m, n) denotes the greatest common divisor of m and n .

K. Hom and \otimes

We continue to consider modules over a ring A . Concerning the direct sum and product, we have

$$\text{Hom}_A\left(\sum_{\lambda} M_{\lambda}, \prod_{\mu} N_{\mu}\right) \cong \prod_{\lambda, \mu} \text{Hom}_A(M_{\lambda}, N_{\mu})$$

and

$$\left(\sum_{\lambda} M_{\lambda}\right) \otimes_A \left(\sum_{\mu} N_{\mu}\right) \cong \sum_{\lambda, \mu} (M_{\lambda} \otimes_A N_{\mu}).$$

Concerning projective and inductive limits we have

$$\text{Hom}_A\left(\lim_{\rightarrow} M_{\lambda}, \lim_{\leftarrow} N_{\mu}\right) \cong \lim_{\leftarrow} \text{Hom}_A(M_{\lambda}, N_{\mu})$$

and

$$\left(\lim_{\rightarrow} M_{\lambda}\right) \otimes_A \left(\lim_{\rightarrow} N_{\mu}\right) = \lim_{\rightarrow} (M_{\lambda} \otimes_A N_{\mu}).$$

An A -homomorphism $f: M \rightarrow M'$ induces a homomorphism $\text{Hom}_A(M', N) \rightarrow \text{Hom}_A(M, N)$ by the assignment $g \rightarrow g \circ f$. An exact sequence $M' \rightarrow M \rightarrow M'' \rightarrow 0$ gives rise to the exact sequence

$$0 \rightarrow \text{Hom}_A(M'', N) \rightarrow \text{Hom}_A(M, N) \rightarrow \text{Hom}_A(M', N). \quad (1)$$

An A -homomorphism $f: N \rightarrow N'$ induces a homomorphism $\text{Hom}_A(M, N) \rightarrow \text{Hom}_A(M, N')$ by the assignments $g \rightarrow f \circ g$, and an exact sequence $0 \rightarrow N' \rightarrow N \rightarrow N''$ gives rise to the exact sequence

$$0 \rightarrow \text{Hom}_A(M, N') \rightarrow \text{Hom}_A(M, N) \rightarrow \text{Hom}_A(M, N''). \quad (2)$$

Let M be a right A -module and N', N, N'' be left A -modules. An A -homomorphism $f: N \rightarrow N'$ induces the homomorphism $1_M \otimes f: M \otimes_A N \rightarrow M \otimes_A N'$, and an exact sequence $N' \rightarrow N \rightarrow N'' \rightarrow 0$ gives rise to the exact sequence

$$M \otimes_A N' \rightarrow M \otimes_A N \rightarrow M \otimes_A N'' \rightarrow 0. \quad (3)$$

Exchanging left and right, we obtain similar results (\rightarrow 52 Categories and Functors B; 200 Homological Algebra).

Let Q be an A -module. If for any exact sequence of A -modules

$$0 \rightarrow M' \rightarrow M \rightarrow M'' \rightarrow 0, \quad (4)$$

the induced sequence

$$0 \rightarrow \text{Hom}_A(M'', Q) \rightarrow \text{Hom}_A(M, Q) \rightarrow \text{Hom}_A(M', Q) \rightarrow 0 \quad (5)$$

is exact, then Q is called an **injective A -module**. This is equivalent to the condition that if M' is an A -submodule of an A -module M , then any A -homomorphism $M' \rightarrow Q$ can be extended to an A -homomorphism $M \rightarrow Q$. Any A -module is an A -submodule of some injective A -module, and any injective A -module is a divisible A -module. If A is a \dagger Dedekind domain, any divisible A -module is an injective A -module.

Let P be an A -module. If for any exact sequence (4), the induced sequence

$$0 \rightarrow \text{Hom}_A(P, M') \rightarrow \text{Hom}_A(P, M) \rightarrow \text{Hom}_A(P, M'') \rightarrow 0 \quad (6)$$

is exact, then P is called a **projective A -module**. This is equivalent to the condition that for any surjective A -homomorphism $g: M \rightarrow M''$ and any A -homomorphism $f: P \rightarrow M''$, there exists an A -homomorphism $h: P \rightarrow M$ satisfying $g \circ h = f$. Any A -module is a factor A -module of some projective A -module. A projective A -module has no torsion element. A free A -module is a projective A -module. In general, an A -module is a projective A -module if and only if it is a direct summand of a free A -module.

Let R be a right A -module. If for any exact sequence (4), the induced sequence

$$0 \rightarrow R \otimes_A M' \rightarrow R \otimes_A M \rightarrow R \otimes_A M'' \rightarrow 0 \quad (7)$$

is exact, then R is called a **flat A -module**. Any projective A -module is a flat A -module. A flat A -module R is called **faithfully flat** if $R \otimes_A M$

$= \{0\}$ implies $M = \{0\}$. A flat right A -module R is faithfully flat if and only if $R \neq R\mathfrak{A}$ for any left ideal \mathfrak{A} ($\neq A$) of A . Let A be a \dagger principal ideal domain. Then an A -module R is flat if and only if R has no torsion element, and R is faithfully flat if and only if R has no torsion element and $R \neq Rp$ for any \dagger prime element p of A . We have the following important examples:

(1) For a commutative ring A and its multiplicatively closed subset S , the \dagger ring of quotients A_S is flat as an A -module. However, A_S is not faithfully flat. For instance, the field of rational numbers \mathbb{Q} is not faithfully flat as a \mathbb{Z} -module.

(2) Let A be a \dagger semilocal ring and \bar{A} be its completion. Then \bar{A} is faithfully flat as an A -module (\rightarrow 284 Noetherian Rings; also [1, 7]).

In the exact sequence (4), if $\text{Im } \varphi = \text{Ker } \psi$ is a direct summand of the A -module M , we say that (4) **splits**. Then (5), (6), and (7) are exact for any A -modules Q, P, R . The exact sequence (4) splits if M' is injective or M'' is projective.

By ${}_A M, M_A$, and ${}_A M_B$, we mean that M is a left A -module, a right A -module, and an A - B -bimodule, respectively. As already stated, ${}_A M_B$ and ${}_A N$ imply ${}_B(\text{Hom}_A(M, N))$, and ${}_A M$ and ${}_A N_B$ imply $(\text{Hom}_A(M, N))_B$. Similarly ${}_B M_A$ and N_A imply $(\text{Hom}_A(M, N))_B$, and M_A and ${}_B N_A$ imply ${}_B(\text{Hom}_A(M, N))$. Furthermore, ${}_B M_A$ and ${}_A N$ imply ${}_B(M \otimes_A N)$, and M_A and ${}_A N_B$ imply $(M \otimes_A N)_B$.

With ${}_B L_A, {}_A M$, and ${}_B N$, we have

$$\text{Hom}_A(M, \text{Hom}_B(L, N)) \cong \text{Hom}_B(L \otimes_A M, N). \quad (8)$$

Similarly, for ${}_A M_B, L_A$, and N_B , we have

$$\text{Hom}_A(L, \text{Hom}_B(M, N)) \cong \text{Hom}_B(L \otimes_A M, N). \quad (8')$$

If B is a commutative ring, (8) and (8') are B -isomorphisms. Furthermore, with $L_A, {}_A M_B$, and ${}_B N$, we have

$$(L \otimes_A M) \otimes_B N \cong L \otimes_A (M \otimes_B N). \quad (9)$$

We denote by M^* the set $\text{Hom}_A(M, A)$ of all linear forms on an A -module M . Then ${}_A M$ implies M_A^* , and M_A implies ${}_A M^*$; the A -module M^* is called the **dual module** of M . A as a left A -module is dual to A as a right A -module, and vice versa. For a family of A -modules $\{M_\lambda\}_{\lambda \in \Lambda}$, we have a canonical correspondence $(\sum_{\lambda \in \Lambda} M_\lambda)^* \cong \prod_{\lambda \in \Lambda} M_\lambda^*$. From this, we have a canonical isomorphism $(M^*)^* \cong M$ for any finitely generated projective A -module M . Many facts concerning this \dagger duality are similar to those valid for linear spaces (\rightarrow 256 Linear Spaces G).

Let A be a commutative ring. Letting $A = B = N$ in (8) and (8'), we have the canonical A -

isomorphisms

$$\text{Hom}_A(M, L^*) \cong \text{Hom}_A(L, M^*)$$

$$\cong (L \otimes_A M)^* = \mathfrak{L}(L, M; A),$$

namely, any bilinear form on $L \times M$ is represented by a linear mapping $M \rightarrow L^*$ or $L \rightarrow M^*$.

L. Extension and Restriction of a Basic Ring

Fix a ring homomorphism $\rho: A \rightarrow B$. We regard B as a B - A -bimodule by defining a right operation of A on B by $b \cdot a = b\rho(a)$ ($a \in A, b \in B$). This bimodule is denoted by B_ρ .

For every left A -module M , we construct the left B -module $\rho^*(M) = B_\rho \otimes_A M$, which is called the **scalar extension** of M by ρ . Every A -homomorphism of A -modules $f: M \rightarrow M'$ induces the B -homomorphism $\rho^*(f) = 1_B \otimes f: \rho^*(M) \rightarrow \rho^*(M')$.

For every left B -module N , we construct the left A -module $\rho_*(N) = \text{Hom}_B(B_\rho, N)$, which is called the **scalar restriction** (or **scalar change**) of N by ρ . By the assignment $h \rightarrow h(1)$, we have a module isomorphism $\text{Hom}_B(B_\rho, N) \cong N$. We identify $\rho_*(N)$ with N under this isomorphism. The operation of A on N is then given as $a \cdot y = \rho(a)y$ ($a \in A, y \in N$). If A is a subring of B and ρ is the canonical injection, then the operation of A on $\rho_*(N)$ is the restriction of the operation of B on N . Every B -homomorphism of B -modules $f: N \rightarrow N'$ induces the A -homomorphism $\rho_*(f): \rho_*(N) \rightarrow \rho_*(N')$. For any left A -module M and left B -module N , an A -linear mapping $f: M \rightarrow \rho_*(N) = N$ is called a **semilinear mapping** with respect to ρ . This means that f is an additive homomorphism satisfying $f(ax) = \rho(a)f(x)$ ($a \in A, x \in M$).

The extension and the restriction of a basic ring are related by the canonical isomorphism $\text{Hom}_A(M, \rho_*(N)) \cong \text{Hom}_B(\rho^*(M), N)$ for an A -module M and a B -module N (\rightarrow equation (8')). An element α of the left-hand side and an element β of the right-hand side are associated by the relation $\alpha(x) = \beta(1 \otimes x)$ ($x \in M$) (\rightarrow 52 Categories and Functors).

Let A and B be commutative rings. Then for A -modules M and M' , we have the canonical B -linear mapping $\rho^*: B \otimes_A \text{Hom}_A(M, M') \rightarrow \text{Hom}_B(B \otimes_A M, B \otimes_A M')$, which is a B -isomorphism if M is a finitely generated free (or more generally, projective) A -module. Using the notation ρ^* , we have $\rho^*(\text{Hom}_A(M, M')) \cong \text{Hom}_B(\rho^*(M), \rho^*(M'))$.

We now give some examples where the basic rings are noncommutative. Let G be a group and H its subgroup. Let ρ denote the homomorphism of group rings $K[H] \rightarrow K[G]$ induced by the canonical injection $H \rightarrow G$, where K is a commutative ring. For any $K[H]$ -module M , $\rho^*(M)$ is called the **induced module**

of M . The representation of G associated with $\rho^*(M)$ is the \dagger induced representation of the representation of H associated with M . Next, we fix a group G and consider a homomorphism $\rho: K[G] \rightarrow \bar{K}[G]$ induced by a homomorphism of commutative rings $\sigma: K \rightarrow \bar{K}$. If $K = \bar{K}$ and σ is an automorphism, then the representation associated with the “scalar extension” $\rho^*(M)$ of a $K[G]$ -module M is the \dagger conjugate representation to the representation associated with M . If $\bar{K} = K/\mathfrak{A}$ (\mathfrak{A} is an ideal of K) and σ is the canonical projection, then the representation over \bar{K} associated with the scalar extension $\rho^*(M)$ of a $K[G]$ -module M is the **reduction modulo \mathfrak{A}** of the representation over K associated with M , and $\rho^*(M)$ is canonically isomorphic to $M/\mathfrak{A}M$. Furthermore, the \dagger localization and the \dagger completion can also be treated under the formulation of scalar extension (\rightarrow 67 Commutative Rings G, 284 Noetherian Rings B).

278 (XIII.23) Monge-Ampère Equations

A. Monge-Ampère Equations

A **Monge-Ampère differential equation** is a second-order partial differential equation of the form

$$Hr + 2Ks + Lt + M + N(rt - s^2) = 0, \quad (1)$$

where H, K, L, M , and N are functions of x, y, z, p , and q , and r, s, t, p , and q represent the partial derivatives

$$r = \frac{\partial^2 z}{\partial x^2}, \quad s = \frac{\partial^2 z}{\partial x \partial y}, \quad t = \frac{\partial^2 z}{\partial y^2},$$

$$p = \frac{\partial z}{\partial x}, \quad q = \frac{\partial z}{\partial y}.$$

The characteristic manifolds are integrals of a system of differential equations defined as follows:

Case (i) $N \neq 0$.

$$\begin{aligned} N dp + L dx + \lambda_1 dy &= 0, \\ N dq + \lambda_2 dx + H dy &= 0, \\ dz - p dx - q dy &= 0, \end{aligned} \quad (2)$$

$$\begin{aligned} N dp + L dx + \lambda_2 dy &= 0, \\ N dq + \lambda_1 dx + H dy &= 0, \\ dz - p dx - q dy &= 0, \end{aligned} \quad (3)$$

where λ_1 and λ_2 are the two roots of the equation $\lambda^2 + 2K\lambda + HL - MN = 0$.

Case (ii) $N = 0, H \neq 0$.

$$\begin{aligned} dy &= \lambda_1 dx, \quad H dp + H \lambda_2 dq + M dx = 0, \\ dz - p dx - q dy &= 0, \end{aligned} \quad (4)$$

$$\begin{aligned} dy &= \lambda_2 dx, \quad H dp + H \lambda_1 dq + M dx = 0, \\ dz - p dx - q dy &= 0, \end{aligned} \quad (5)$$

where λ_1 and λ_2 are the two roots of the equation $H\lambda^2 - 2K\lambda + L = 0$.

Case (iii) $N = 0, H = 0, L \neq 0$.

$$\begin{aligned} dx &= 0, \quad M dy + 2K dp + L dq = 0, \\ dz - p dx - q dy &= 0, \end{aligned} \quad (6)$$

$$\begin{aligned} 2K dy - L dx &= 0, \quad M dy + L dq = 0, \\ dz - p dx - q dy &= 0. \end{aligned} \quad (7)$$

Case (iv) $N = 0, H = 0, L = 0$.

$$\begin{aligned} dx &= 0, \quad 2K dp + M dy = 0, \\ dz - p dx - q dy &= 0, \end{aligned} \quad (8)$$

$$\begin{aligned} dy &= 0, \quad 2K dq + M dx = 0, \\ dz - p dx - q dy &= 0. \end{aligned} \quad (9)$$

A manifold $x(\lambda), y(\lambda), z(\lambda), p(\lambda), q(\lambda)$ that satisfies the system (2), (3) of differential equations for case (i), (4), (5) for case (ii), (6), (7) for case (iii), or (8), (9) for case (iv) is a characteristic manifold of equation (1).

The following result is known concerning Monge-Ampère equations: The union of surface elements of an integral surface of (1) is generated in two ways by characteristic manifolds depending on one parameter. Conversely,

if a manifold, each element of which is composed of a point of a surface S and the tangent plane at that point, is generated by a family of characteristic manifolds depending on one parameter, then the surface S is an integral surface of (1).

B. Intermediate Integrals

If a relation $dV(x, y, z, p, q) = 0$ is a consequence of a system of differential equations of characteristic manifolds, for example, in case (i) when V satisfies

$$\begin{aligned} N(\partial V / \partial x + p \partial V / \partial z) - L \partial V / \partial p - \lambda_2 \partial V / \partial q &= 0, \\ N(\partial V / \partial y + q \partial V / \partial z) - \lambda_1 \partial V / \partial p - H \partial V / \partial q &= 0, \end{aligned}$$

$V(x, y, z, p, q) = c$ (c an arbitrary constant) is called an **integral** of the system of differential equations. (i) If $V = c$ is an integral of a system of differential equations of characteristic manifolds, the solution $z(x, y)$ of $V = c$ considered anew as a partial differential equation of the first order is a solution of (1). Conversely, if every solution of $V = c$ (excepting *singular ones) satisfies equation (1), $V = c$ is an integral of a system of differential equations of characteristic manifolds. (ii) If $u(x, y, z, p, q)$ and $v(x, y, z, p, q)$ are two integrals of a system of differential equations of characteristic manifolds, then for any arbitrary function φ , $\varphi(u, v)$ is also an integral. Thus, as a consequence of (i), every solution $z(x, y)$ of $\varphi(u, v) = 0$ is also a solution of (1). The converse is also true, namely, for every solution z of (1) we can find a function φ such that $z(x, y)$ is also a solution of $\varphi(u, v) = 0$. The relation $\varphi(u, v) = 0$ is called an **intermediate integral** of (1). Sometimes an integral of a system of differential equations of characteristic manifolds is also called an intermediate integral. If each of the two systems of differential equations defining the characteristic manifolds has an intermediate integral, then the two intermediate integrals $\varphi(u, v) = 0$ and $\psi(u, v) = 0$ form a *complete system of partial differential equations of the first order. Integrating this complete system, the *general solution of equation (1) is obtained.

279 (VII.16) Morse Theory

A. General Remarks

We are interested in smooth functions on a smooth manifold of dimension m that have only the simplest critical points. Here, "smooth" means differentiable of class C^∞ .

Such a function $f: M \rightarrow \mathbf{R}$ enables us to investigate the topology of M . The decomposition of M into level sets of f contains a lot of topological information on M . For instance, it is shown that M is homotopy equivalent to a CW complex that is determined by critical points of f ; furthermore the Euler characteristic of M can be computed by means of f , because the critical points are related to the homology groups of M . These types of investigations, called **Morse theory**, were originated by H. Poincaré [1] and G. D. Birkhoff [2] and then developed into the form we see today by M. Morse [3]. An excellent exposition of this theory has been given by J. Milnor [4]. R. S. Palais [5] has extended the theory to Hilbert manifolds. Morse theory has been fruitfully applied to differential topology and differential geometry.

B. Critical Points of Functions on Manifolds

For a point $p \in M$, M_p is by definition the tangent space to M at p . Let f be a smooth real-valued function on M . A point $p \in M$ is called a **critical point** of f if the induced mapping $f_*: M_p \rightarrow \mathbf{R}_{f(p)}$ is zero at p . For every local chart (x_1, \dots, x_m) around a critical point p of f with $p = (0, \dots, 0)$,

$$\frac{\partial f}{\partial x_1}(0) = \dots = \frac{\partial f}{\partial x_m}(0) = 0.$$

The value $f(p)$ is then called a **critical value** of f . If the matrix $(\partial^2 f / \partial x_i \partial x_j(0))$ is invertible, then the point is called a **nondegenerate critical point**, and if the matrix is not invertible, then the point is said to be **degenerate**. These notions are independent of the choice of local charts around p . The above matrix is called the **Hessian** of f at p . The nullity and index of the Hessian of f at p are called the **nullity** and **index** of f at p , respectively. The function f has a local minimum at a nondegenerate critical point of index 0, and a local maximum at a nondegenerate critical point of index n .

A smooth function f on M is called a **Morse function** if it satisfies: (A1) Every critical point of f is nondegenerate. The **Morse lemma** states that if p is a nondegenerate critical point of f

and if the index of f at p is λ , then there exists a local chart (y_1, \dots, y_m) around p with $p = (0, \dots, 0)$ such that f is expressed as

$$f(y) = f(p) - (y_1)^2 - \dots - (y_\lambda)^2 + (y_{\lambda+1})^2 + \dots + (y_m)^2.$$

C. The Existence of Morse Functions

Let M be a compact smooth m -dimensional manifold without boundary. The existence of Morse functions on M is shown by embedding M into \mathbf{R}^n for a sufficiently large n . For convenience, M will be here identified with its embedded image. At each point $p \in M$ the set v_p of all unit normals forms an $(n-m-1)$ -dimensional unit sphere, and $v(M) = \bigcup_{p \in M} v_p$ is a smooth $(n-1)$ -dimensional compact manifold. Let S be the unit hypersphere in \mathbf{R}^n around the origin. The Gauss normal mapping $\varphi: v(M) \rightarrow S$ sends each point $(p, v(p)) \in v(M)$ to $v \in S$ via a canonical parallel translation of \mathbf{R}^n . Since φ is smooth, the Sard theorem implies that the set E of all critical values of φ has measure zero on S . Thus φ_* at every $(p, v(p)) \in \varphi^{-1}(v)$ has maximal rank if v is taken in $S - E$. For every fixed $v \in S - E$ let $h_v: M \rightarrow \mathbf{R}$ be defined by $h_v(x) = \langle v, x \rangle$, $x \in M$, where $\langle \cdot, \cdot \rangle$ denotes the canonical inner product of \mathbf{R}^n . Then h_v is a Morse function. To see this let dS , dv , and dM be volume elements of S , v , and M , respectively. Then $dv \wedge dM$ is a volume element of $v(M)$, and the function $G: v(M) \rightarrow \mathbf{R}$ is obtained by the relation $\varphi^* dS = G(x, v(x)) dv \wedge dM$. $G(x, v(x))$ is called the **Lipschitz-Killing curvature** at $v(x) \in v_x$. If $A(v(x))$ denotes the second fundamental form of M with respect to $v(x)$, then $G(x, v(x)) = (-1)^m \det(A(v(x)))$ (Chern and Lashof [6]). Every critical point $p \in M$ of h_v for $v \in S - E$ has a normal $v(p)$ to M at p , and the Hessian of h_v is given by $A(v(p))$. Thus $G(p, v(p)) \neq 0$ ensures the nondegeneracy at p [6].

Another approach to the construction of Morse functions is to find for a given embedding of M into \mathbf{R}^n an open dense set $U \subset \mathbf{R}^n$ such that the Euclidean distance d_x from any fixed point x on U to points on M has no degenerate critical points on M . In this case $d_x^{-1}((-\infty, a])$ is compact for all $a \in \mathbf{R}$. It is also possible to construct Morse functions on compact manifolds with boundary as well as on noncompact manifolds. But a striking result of A. Phillips states that there exists a Morse function on every noncompact manifold which has no critical points [7].

For a pair of smooth manifolds M, N let $C^\infty(M, N)$ be the set of all smooth mappings from M to N . The **weak** (or **compact-open**) C^∞

topology on $C^\infty(M, N)$ is generated by the sets defined as follows. Let $f \in C^\infty(M, N)$, and let (U, φ) and (V, ψ) be charts of M and N , respectively. Let $K \subset U$ be a compact set such that $f(K) \subset V$. For $\varepsilon \in (0, \infty)$, a weak \dagger subbasic neighborhood $N^\infty(f; (U, \varphi), (V, \psi), K, \varepsilon)$ of f is defined to be the set of all smooth mappings $g \in C^\infty(M, N)$ such that (1) $g(K) \subset V$, (2) $\|D^k(\varphi \circ f \circ \psi^{-1})(x) - D^k(\varphi \circ g \circ \psi^{-1})(x)\| < \varepsilon$, $x \in \varphi(K)$, $k = 1, 2, \dots$, where D^k denotes the k th derivative with respect to the coordinates. The weak C^∞ topology is thus defined on $C^\infty(M, N)$, and the space with this topology is denoted by $C_w^\infty(M, N)$. It follows from the construction of the embedding in the Whitney embedding theorem that the set of all smooth embeddings of compact M into \mathbf{R}^n is dense in $C_w^\infty(M, \mathbf{R}^n)$ if $n > 2 \dim M$. Moreover, the set of all Morse functions on a compact M forms an open dense set in $C_w^\infty(M, \mathbf{R})$ (Nagano [8], Hirsh [9], Auslander and MacKenzie [10]).

D. Decomposition of M by a Morse Function

To decompose M into levels of a Morse function we now consider the process of \dagger attaching a handle. Let M be a compact manifold with \dagger boundary ∂M . Let D^s be the s -disk, and let $g: (\partial D^s) \times D^{m-s} \rightarrow \partial M$ be an \dagger embedding. Then a \dagger manifold $X(M; g; s)$ with a handle attached by g is defined as the quotient set obtained from the disjoint union $M \cup (D^s \times D^{m-s})$ by identifying points in $\partial D^s \times D^{m-s}$ and their images under g and equipped with a natural differentiable structure. Similarly, if $g_i: (\partial D_i^s) \times D_i^{m-s_i} \rightarrow \partial M$ ($i = 1, \dots, k$) are embeddings with disjoint images, we can define the \dagger handlebody $X(M; g_1, \dots, g_k; s_1, \dots, s_k)$ [11].

For an $f \in C^\infty(M, \mathbf{R})$ and for $a, b \in f(M)$ with $a < b$ let $M^a = \{x \in M \mid f(x) \leq a\}$ and $M_a^b = \{x \in M \mid a \leq f(x) \leq b\}$. M_a^b is called a **level set** of f . For a Morse function f on a compact manifold M without boundary, the following fundamental facts are known [4]: (1) The **first fundamental theorem**. If M_a^b contains no critical points, then M_a^b is diffeomorphic to $M_a^a \times [a, b]$; (2) The **second fundamental theorem**. Let $c \in (a, b)$ be a unique critical value in $[a, b]$, and let $p_1, \dots, p_k \in M_c^c$ be critical points of f with p_i having index λ_i . Then M^b is diffeomorphic to $X(M^a; f_1, \dots, f_k, \lambda_1, \dots, \lambda_k)$ for suitable embeddings f_1, \dots, f_k . It follows from the existence of Morse functions and from (1) and (2) that every compact manifold can be obtained by successively attaching handles to a disk (\rightarrow 114 Differential Topology). Furthermore, if M admits a Morse function with only two critical points, then M is homeomorphic to a sphere (Reeb [12]).

Concerning the homotopy types of M and

M^a we have the following: (3) If $c \in f(M)$ is a critical value of f with points p_1, \dots, p_k with p_i having index λ_i and if $M_c^{c+\varepsilon}$ is compact for $\varepsilon > 0$ and contains no critical points other than p_1, \dots, p_k , then $M^{c+\varepsilon}$ has the same homotopy type as $M^{c-\varepsilon} \cup e^{\lambda_1} \cup \dots \cup e^{\lambda_k}$, where e^{λ_j} ($j = 1, \dots, k$) are λ_j -cells. (4) Assume that a Morse function f on a (not necessarily compact) M satisfies: (A2) M^a is compact for all $a \in \mathbf{R}$. Then by choosing a sequence $a_1 < a_2 < \dots$ of regular values of f and applying (3) to each $M_{a_i}^{a_{i+1}}$, we see that M has the same homotopy type as that of a CW complex ζ , where the number of λ -cells belonging to ζ is the same as that of critical points of index λ of f .

Moreover, we have the following Morse inequalities: (5) Let f be a Morse function on a compact M . If M_λ is the number of critical points of f on M of index λ , and if R_λ is a λ -dimensional \dagger Betti number of M , then

$$M_0 \geq R_0,$$

$$M_1 - M_0 \geq R_1 - R_0,$$

$$M_\lambda - M_{\lambda-1} + \dots + (-1)^\lambda M_0$$

$$\geq R_\lambda - R_{\lambda-1} + \dots + (-1)^\lambda R_0, \quad 1 \leq \lambda \leq n-1,$$

$$M_n - M_{n-1} + \dots + (-1)^n M_0$$

$$= R_n - R_{n-1} + \dots + (-1)^n R_0.$$

In particular, we have $M_k \geq R_k$ for all k . By using these facts S. Smale obtained an affirmative solution of the \dagger Poincaré conjecture in high dimensions [11, 13].

The concept of critical manifolds in the sense of Bott [14] is stated as follows: Let M be a compact manifold embedded into an open set $U \subset \mathbf{R}^k$. Let $f: U \rightarrow \mathbf{R}$ be a smooth function. M is called a **nondegenerate critical manifold** of f on U if (1) all points of M are critical points of f and (2) the nullity of all $x \in M$ is equal to $\dim M$. When M is such a nondegenerate critical manifold of f on U , f is constant on M , and the index λ of f at x is well defined and is the same at all points on M . The \dagger Poincaré polynomial is expressed as $P(M; t) = \sum t^k \dim H^k(M)$. The Morse polynomial is defined by $\mathfrak{M}(f; t) = \sum_N t^{\lambda_N} P(N; t)$, where N runs over all critical manifolds of f and λ_N is the index of N . Under certain conditions for orientability along each nondegenerate critical manifold of f , we have again the **Morse inequality**

$$\mathfrak{M}(f; t) \geq P(M; t).$$

E. Morse Theory on Hilbert Manifolds

Let M be a \dagger Hilbert manifold, and let $f: M \rightarrow \mathbf{R}$ be a smooth function. The Hessian $\partial^2 f_p$ of f at a critical point of f is a symmetric bilinear

form on M_p given by

$$\partial^2 f_p(u, v) = d^2(f \circ \varphi^{-1})(d\varphi_p(u), d\varphi_p(v)),$$
$$u, v \in M_p,$$

where φ is a coordinate mapping of a local chart around p . The **index (coindex)** of f at a critical point $p \in M$ of f is defined to be the supremum of dimensions of subspaces of M_p on which $\partial^2 f_p$ is negative (positive) definite. The self-adjoint bounded operator A which represents $\partial^2 f_p$ is given by $\partial^2 f_p(u, v) = \langle u, A(v) \rangle_p$. If A is invertible, then f is said to be **nondegenerate** at p . These notions do not depend on the choice of local charts around p .

The Morse lemma has been generalized to a Riemannian Hilbert manifold M by R. Palais and S. Smale [15] as follows. Let f be a smooth function defined on M . If $x \in M$ is a nondegenerate critical point of f then there exist a chart φ around x and a projection P such that for y near x

$$f(y) = f(x) + \|P\varphi(y)\|^2 - \|(I - P)\varphi(y)\|^2.$$

The above result has been extended to critical manifolds [16]. A connected submanifold N of a Hilbert manifold M is called a **nondegenerate critical manifold** of $f: M \rightarrow \mathbf{R}$ if (1) every point $p \in M$ is a critical point of f and (2) for each $p \in M$ there exists a closed subspace E_p of M_p such that $M_p = N_p \oplus E_p$ and the Hessian form restricted to E_p is nondegenerate. Let $v = (\pi, E, N)$ be a smooth Hilbert-space bundle over a compact connected manifold N , and let $\langle \cdot, \cdot \rangle$ be a Riemannian structure for v . Assume that a smooth function $f: E \rightarrow \mathbf{R}$ has the zero section of v as a nondegenerate critical manifold. Then there exist a tubular neighborhood $v_\varepsilon = \{v \in E \mid \|v\| < \varepsilon\}$ of the zero section in v and a fiber-preserving diffeomorphism $\psi: v_\varepsilon \rightarrow \psi(v_\varepsilon)$ and an orthogonal bundle projection P such that for $v \in v_\varepsilon$

$$f \circ \psi(v) = f(N) + \|Pv\|^2 - \|(I - P)v\|^2.$$

Let us assume that (B) M is a complete Riemannian manifold, and (C) (**Palais-Smale condition**) if f is bounded on a set $S \subset M$ and if the norm $\|\nabla f\|$ of the \dagger gradient vector of f has infimum 0 on S , then there is a critical point of f on the closure \bar{S} of S . Since M is not locally compact, condition (C) is required. In order to prove the first and second fundamental theorems of Morse theory it is necessary that the integral curves of ∇f exist, and (C) ensures their existence. Namely, under conditions (A1), (B), and (C), one of the following two facts follows for any $b \in f(M)$ and for any regular point $p \in M^b$: (1) The integral curve $c: [0, r] \rightarrow M^b$ of ∇f with $c(0) = p$ exists, and $f \circ c(r) = b$ holds for some $r \in [0, \infty)$; (2) the integral curve $c: [0, \infty) \rightarrow M^b$ of ∇f exists and

$\lim_{t \rightarrow \infty} c(t)$ exists such that the limit point $c(\infty) = \lim_{t \rightarrow \infty} c(t) \in M^b$ is a critical point of f . These facts imply that the first fundamental theorem of Morse theory holds if M_a^b does not contain any critical point of f , and also the second fundamental theorem holds if M_a^b has only nondegenerate critical points on M_c^c for some $c \in (a, b)$. Furthermore, assume that $f: M \rightarrow \mathbf{R}$ and M satisfies (A1), (B), and (C), and let $a, b \in f(M)$ be regular values with $a < b$. If for each nonnegative integer λ , R_λ is the λ th Betti number of M_a^b , and if M_λ^b is the number of critical points of index λ of f in M_a^b , then the **Morse inequality** holds:

$$M_0 \geq R_0,$$
$$M_1 - M_0 \geq R_1 - R_0,$$
$$\dots,$$
$$\sum_{k=0}^{\lambda} (-1)^{\lambda-k} M_k \geq \sum_{k=0}^{\lambda} (-1)^{\lambda-k} R_k,$$
$$\dots,$$
$$\sum_{k=0}^{\infty} (-1)^k M_k = \sum_{k=0}^{\infty} (-1)^k R_k.$$

In particular, $M_\lambda \geq R_\lambda$ holds for all λ . If f is bounded below, then the λ th Betti number R_λ^* of M^b and the number M_λ^* of all critical points of f with index λ in M^b satisfy $M_\lambda^* \geq R_\lambda^*$ for all λ .

F. Morse Theory of Path Spaces

Morse theory on Hilbert manifolds applies to the energy functions on Riemannian Hilbert manifolds which consist of all H_1 -curves on a compact Riemannian manifold M , and the theory is useful for proving the existence of closed geodesics on M .

Let M be a smooth manifold, and let $I = [0, 1]$. Let $H_1(I, M)$ be the set of all continuous curves $\sigma: I \rightarrow M$ such that for each local chart (V, φ) of M , $\varphi \circ \sigma$ is absolutely continuous and $\|(\varphi \circ \sigma)'\|$ is locally square integrable. In particular, if $M = \mathbf{R}^m$, then $H_1(I, \mathbf{R}^m)$ is a Hilbert space with the inner product

$$(\sigma, \rho)_1 := (\sigma(0), \rho(0)) + \int_I (\sigma(t), \rho(t)) dt,$$
$$\sigma, \rho \in H_1(I, \mathbf{R}^m).$$

For each $\sigma \in H_1(I, M)$, set $H_1(I, M)_\sigma = \{X \in H_1(I, TM) \mid X(t) \in M_{\sigma(t)}, t \in I\}$, where TM is by definition the \dagger tangent bundle over M . For any fixed pair of points $p, q \in M$, let $\Omega(M; p, q) = \{\sigma \in H_1(I, M) \mid \sigma(0) = p, \sigma(1) = q\}$, and for each $\sigma \in \Omega(M; p, q)$, let $\Omega(M; p, q)_\sigma = \{X \in H_1(I, M)_\sigma \mid X(0) = 0 \in M_p, X(1) = 0 \in M_q\}$. Then $H_1(I, M)_\sigma$ forms a vector space, and $\Omega(M; p, q)_\sigma$ is a subspace of $H_1(I, M)_\sigma$. M can be embedded into \mathbf{R}^n for sufficiently large n by the Whitney

embedding theorem [17]. Then we have the following facts [17]: (1) $H_1(I, M) = \{\sigma \in H_1(I, \mathbf{R}^n) \mid \sigma(I) \subset M\}$, (2) $H_1(I, M)$ is a closed submanifold of $H_1(I, \mathbf{R}^n)$, (3) $\Omega(M; p, q)$ is a closed submanifold of $H_1(I, M)$, (4) the tangent space to $H_1(I, M)$ at each point $\sigma \in H_1(I, M)$ is $H_1(I, M)_\sigma$, (5) the tangent space to $\Omega(M; p, q)$ at each point $\sigma \in \Omega(M; p, q)$ is $\Omega(M; p, q)_\sigma$. Here M is identified with the embedded image in \mathbf{R}^n . Thus $H_1(I, M)$ and $\Omega(M; p, q)$ carry the structure of a Hilbert manifold, and they are independent of the choice of embeddings [17].

The energy functions on $H_1(I, M)$ and $\Omega(M; p, q)$ play important roles in the development of Morse theory. M is now assumed to be a complete Riemannian manifold. It follows from the Nash isometric embedding theorem (\rightarrow 365 Riemannian Submanifolds B) that M is isometrically embedded into \mathbf{R}^n for a sufficiently large n . $H_1(I, \mathbf{R}^n)$ carries a complete Riemannian metric in a natural way, and $H_1(I, M)$ becomes a complete Riemannian manifold with the metric induced from $H_1(I, \mathbf{R}^n)$. Similarly $\Omega(M; p, q)$ admits a complete Riemannian metric. Then the **energy function** $E: H_1(I, M) \rightarrow \mathbf{R}$ is defined to be

$$E(\sigma) := \frac{1}{2} \int_I \langle \sigma', \sigma' \rangle dt,$$

where $\langle \cdot, \cdot \rangle$ is the inner product induced from the Riemannian structure of M . Then the Palais-Smale condition (C) is satisfied for E on $H_1(I, M)$. That is, if a sequence $\{\sigma_k\}$ on $H_1(I, M)$ satisfies: (1) $\{E(\sigma_k)\}$ is bounded above; and (2) $\nabla E(\sigma_k) \rightarrow 0$ as $k \rightarrow \infty$, then there is a subsequence $\{\sigma_{k'}\}$ of $\{\sigma_k\}$ such that $\{\sigma_{k'}\}$ converges to a critical point $\sigma \in H_1(I, M)$ of E . Also, condition (C) is fulfilled for the energy function on $\Omega(M; p, q)$.

For a fixed pair of points $p, q \in M$, let $\Omega = \Omega(M, p, q)$. Let $\sigma \in \Omega$ be a critical point of E . A tangent vector W to Ω at $\sigma: I \rightarrow M$ with $\sigma(0) = p, \sigma(1) = q$ is a \dagger piecewise differentiable vector field along σ such that $W(0) = 0 \in M_p$ and $W(1) = 0 \in M_q$. A **proper variation** $\alpha: (-\varepsilon, \varepsilon) \times I \rightarrow M$ along σ which is associated with W satisfies the following: (1) $\alpha(0, t) = \sigma(t), t \in I$; (2) there exists a finite partition $0 = t_0 < t_1 < \dots < t_k = 1$ of I such that $\alpha|(-\varepsilon, \varepsilon) \times [t_{i-1}, t_i]$ is differentiable for all $i = 1, \dots, k$; (3) $\alpha(u, 0) = p$ and $\alpha(u, 1) = q$ hold for all $u \in (-\varepsilon, \varepsilon)$; and (4) $\partial\alpha(0, t)/\partial u = W(t), t \in I$. It follows from the first variation formula (\rightarrow 178 Geodesics A) that $\sigma \in \Omega$ is a critical point of E if and only if σ is a geodesic on M . Let $W_1, W_2 \in \Omega_\sigma$, and let U be an open set in \mathbf{R}^2 around the origin. Then a **proper variation** $\alpha: U \times I \rightarrow M$ along σ that is associated with W_1 and W_2 satisfies the following: (1) $\alpha(0, t) = \sigma(t), t \in I$; (2) there exists a finite partition $0 = t_0 < t_1 < \dots < t_k = 1$ of I such

that $\alpha|U \times [t_{i-1}, t_i]$ is differentiable for all $i = 1, \dots, k$; (3) $\alpha(u_1, u_2, 0) = p, \alpha(u_1, u_2, 1) = q$ for all $(u_1, u_2) \in U$; and (4) $\partial\alpha(0, 0, t)/\partial u_1 = W_1(t), \partial\alpha(0, 0, t)/\partial u_2 = W_2(t), t \in I$. Then the **Hessian** E_{**} of E at σ is given by

$$E_{**}(W_1, W_2) = \frac{1}{2} \frac{\partial^2 E(\bar{\alpha}(u_1, u_2))}{\partial u_1 \partial u_2} \Big|_{(0,0)},$$

where $\bar{\alpha}(u_1, u_2) \in \Omega$ is by definition the curve $\bar{\alpha}(u_1, u_2)(t) = \alpha(u_1, u_2, t)$. The second variation formula (\rightarrow 178 Geodesics A) then gives

$$E_{**}(W_1, W_2) = - \sum \langle W_2(t), \Delta_t W_1'(t) \rangle - \int_I \langle W_2, W_1'' + R(W_1, \sigma')\sigma' \rangle dt,$$

where $\Delta_t W_1'(t) = W_1'(t+0) - W_1'(t-0)$. We have the **Morse index theorem**, which states: (1) The \dagger null space of E at a critical point σ is the linear space spanned by all Jacobi fields (\rightarrow 178 Geodesics A) along σ that vanish at 0 and 1; (2) if $\{\sigma(s_1), \sigma(s_2), \dots, \sigma(s_l)\}$ ($0 < s_1 < s_2 < \dots < s_l < 1$) is the set of all points conjugate to $\sigma(0)$ along σ and if λ_i is the multiplicity of the conjugate point $\sigma(s_i)$, then the index of E at σ is equal to $\lambda_1 + \dots + \lambda_l$. It follows from the Sard theorem together with the differentiability of the exponential mapping on M that except for a set of measure zero in $M \times M, p, q$ can be chosen so that p, q is not a conjugate pair along any geodesic in Ω . Then all critical points of E are nondegenerate, and for any $c > 0, \Omega^c = \{\omega \in \Omega \mid E(\omega) = c\}$ contains at most finitely many nondegenerate critical points with finite indices.

G. Existence of Closed Geodesics

Let M be a compact Riemannian manifold. By replacing I with the circle S^1 , we consider a Hilbert manifold $\Lambda(M) = H_1(S^1, M)$. $\Lambda(M)$ carries the structure of a complete Riemannian manifold. Every point $p \in M$ is naturally embedded in $\Lambda(M)$ as a point curve, and M is a totally geodesic submanifold of $\Lambda(M)$. A point $\sigma \in \Lambda(M)$ is a critical point of the energy function $E: \Lambda(M) \rightarrow \mathbf{R}$ if and only if σ is a closed geodesic of M . It is known that E satisfies the Palais-Smale condition (C). The index and nullity of E at a critical point σ is finite. Since M is compact, the fundamental length \sqrt{c} of M is positive and $\Lambda^c = \{\sigma \in \Lambda(M) \mid E(\sigma) \leq c\}$ is a \dagger deformation retract of $M \subset \Lambda(M)$ by means of the deformation along the integral curves of $-\nabla E$.

If M is not simply connected, then each nontrivial element of the \dagger fundamental group of M represents a class of homotopic curves in

which there is a closed geodesic whose length realizes the infimum of all these curves. If M is simply connected, then there is a minimum integer k for which $\pi_k(M) \neq 0$. Clearly, $\pi_{k-1}(\Lambda(M)) \approx \pi_k(M) \neq 0$. Suppose that E has no positive critical value. Then $\Lambda(M)$ is a deformation retract of M , a contradiction. Therefore there exists at least one closed geodesic on every compact Riemannian manifold (Lyusternik and Fet [18]).

Proof of the existence of many closed geodesics on M is difficult due to the following: (1) There is a continuous $O(2)$ action on $\Lambda(M)$ that assigns $\sigma \in \Lambda(M)$ and $\alpha \in O(2)$ to the curve $t \rightarrow \sigma(t + \alpha)$, $t \in S^1$; (2) for each integer k and for each critical point $\sigma \in \Lambda(M)$, the curve $t \rightarrow \sigma(kt)$ is a critical point with energy $k^2 E(\sigma)$.

A remarkable result has been obtained by Lyusternik and Shnirel'man [19], which states that there are at least three closed geodesics on every simply connected compact manifold of dimension 2. Fet then proved that there exist at least two closed geodesics on a compact manifold if all critical points of E on $\Lambda(M)$ are nondegenerate [20]. By developing a precise argument concerning the Morse lemma around an isolated degenerate critical point $\sigma \in \Lambda(M)$ of E , Gromoll and Meyer have proved that there exist infinitely many closed geodesics if the sequence of Betti numbers $\{b_i(\Lambda(M))\}$ with respect to any field is unbounded [21]. If $A: M \rightarrow M$ is a certain isometry, then there are also infinitely many A -invariant closed geodesics if the Betti numbers of the space of A -invariant H_1 -curves are not bounded [22, 23]. By investigating the Z_2 -cohomology of $\Lambda(M)$ of compact symmetric spaces, Ziller has proved that if M has the same homotopy type as that of a symmetric space of rank ≥ 2 , then M has infinitely many closed geodesics [24].

Many attempts have been made by W. Klingenberg and others to prove the existence of infinitely many geometrically distinct closed geodesics on every compact Riemannian manifold [25].

280 (XVIII.9) Multivariate Analysis

A. General Remarks

Multivariate analysis consists of methods of statistical analysis of multivariate observations represented by a collection of points in a finite-dimensional Euclidean space \mathbb{R}^p . With the development of powerful computers, multivariate techniques are beginning to be utilized in many fields of science and technology.

B. The Multivariate Linear Model

The multivariate linear model is an immediate extension of the univariate linear model. Suppose that $\mathbf{X} = (\mathbf{X}^{(1)} \dots \mathbf{X}^{(n)})$ denotes the $p \times n$ matrix of n observations of p -dimensional data. Suppose that it can be expressed as

$$\mathbf{X} = \mathbf{B}\mathbf{Z} + \mathbf{U}, \quad (1)$$

where \mathbf{B} is a $p \times m$ matrix of unknown parameters, \mathbf{Z} is a known $m \times n$ matrix of independent variables, and \mathbf{U} is a $p \times n$ matrix of errors. We assume that (i) the \dagger expectations of the elements of \mathbf{U} are zero, that is, the $p \times n$ matrix $E(\mathbf{U}) = 0$, and call the relation (1) a **multivariate linear model**. We usually assume further that (ii) the column vectors $\mathbf{U}^{(i)}$, $i = 1, \dots, n$, of \mathbf{U} are independent and identically distributed, and that (iii) $\mathbf{U}^{(i)}$ is distributed according to a multivariate \dagger normal distribution with \dagger covariance matrix Σ . Analogous to the univariate case, the \dagger least squares estimator $\hat{\mathbf{B}}$ of \mathbf{B} is defined to be the $p \times m$ matrix that minimizes

$$\text{tr}(\mathbf{X} - \mathbf{B}\mathbf{Z})(\mathbf{X} - \mathbf{B}\mathbf{Z})'$$

and is given explicitly by

$$\hat{\mathbf{B}} = \mathbf{X}\mathbf{Z}'(\mathbf{Z}\mathbf{Z}')^{-1} \quad \text{when} \quad |\mathbf{Z}\mathbf{Z}'| \neq 0.$$

Here the symbol $'$ means the transpose of a matrix. Also, an unbiased estimator of Σ is given by

$$\hat{\Sigma} = \mathbf{Q}_e/(n-m), \quad \mathbf{Q}_e = \mathbf{X}\mathbf{X}' - \hat{\mathbf{B}}\mathbf{Z}\mathbf{X}'.$$

$\hat{\mathbf{B}}$ is an unbiased estimator of \mathbf{B} under the assumption (i) above and is the \dagger best linear unbiased estimator under (i) and (ii), while $\hat{\Sigma}$ is unbiased when (i) and (ii) are assumed. Under the assumptions (i)–(iii), $\hat{\mathbf{B}}$ and $\hat{\Sigma}$ form a set of complete \dagger sufficient statistics; hence they are \dagger uniformly minimum variance unbiased estimators. Also under (i)–(iii), elements of $\hat{\mathbf{B}}$ are normally distributed, and their covariance can be expressed by

$$\Sigma \otimes M \quad (\otimes \text{ denotes the } \dagger \text{Kronecker product}),$$

where $M = (\mathbf{Z}\mathbf{Z}')^{-1}$. Applying \dagger Cochran's theorem for the multivariate case, \mathbf{Q}_e is shown to be distributed according to a \dagger Wishart distribution with $n-m$ degrees of freedom.

To test the hypothesis $\mathbf{B} = \mathbf{B}_0$ under (i)–(iii), we put $\mathbf{Q}_B = (\hat{\mathbf{B}} - \mathbf{B}_0)\mathbf{Z}\mathbf{Z}'(\hat{\mathbf{B}} - \mathbf{B}_0)'$ and have $(\mathbf{X} - \mathbf{B}_0\mathbf{Z})(\mathbf{X} - \mathbf{B}_0\mathbf{Z})' = \mathbf{Q}_B + \mathbf{Q}_e$, where \mathbf{Q}_B and \mathbf{Q}_e are independently distributed. The distribution of \mathbf{Q}_B is a Wishart distribution with m degrees of freedom when the hypothesis is true, and a \dagger noncentral Wishart distribution when $\mathbf{B} \neq \mathbf{B}_0$. Based on this fact, several procedures have been proposed. If we require the invariance of procedures with respect to linear transformations of the coordinates of p -dimensional vectors, the roots $\lambda_1, \dots, \lambda_p$ of the \dagger characteristic equation $|\mathbf{Q}_B - \lambda \mathbf{Q}_e| = 0$ form a \dagger maximal invariant statistic; hence the testing procedures should be defined in terms of these roots (\rightarrow 396 Statistic I). Also, the consideration of \dagger power leads to procedures that reject the hypothesis when these roots are large. Commonly used test statistics are (1) the \dagger likelihood ratio test $W = |\mathbf{Q}_e|/|\mathbf{Q}_B + \mathbf{Q}_e| = \prod_i (1 + \lambda_i)^{-1}$ (S. S. Wilks); (2) $\text{tr} \mathbf{Q}_e^{-1} \mathbf{Q}_B = \sum \lambda_i$ (D. N. Lawley and H. Hotelling); (3) $\max \lambda_i$ (S. N. Roy); (4) $\text{tr} \mathbf{Q}_B(\mathbf{Q}_B + \mathbf{Q}_e)^{-1} = \sum \lambda_i(1 + \lambda_i)^{-1}$ (K. C. S. Pillai). Pillai's trace test (4) is locally the most powerful invariant; Wilks's likelihood ratio test (1) has the maximum Bahadur efficiency. The power functions of the tests (1)–(3) have the monotonicity property, namely, they are monotonically nondecreasing with respect to each eigenvalue of $\Omega = \Sigma^{-1}(\mathbf{B} - \mathbf{B}_0)\mathbf{Z}\mathbf{Z}'(\mathbf{B} - \mathbf{B}_0)'$, the matrix of noncentrality parameters for \mathbf{Q}_B . The monotonicity for Pillai's test (4) is known to hold only for restricted cases where the critical value c for the acceptance region $\text{tr} \mathbf{Q}_B(\mathbf{B}_B + \mathbf{Q}_e)^{-1} \leq c$ should satisfy $0 \leq c \leq 1$. All the tests (1)–(4) are unbiased. With respect to 0–1 loss, the tests (1) and (4) are \dagger admissible Bayes and the tests (2) and (3) are \dagger admissible. Tests based on $\min \lambda_i$ are inadmissible.

Small-sample distributions of these statistics are complicated but when $n \rightarrow \infty$, $n \log W$, $n \text{tr} \mathbf{Q}_B \mathbf{Q}_e^{-1}$, and $n \text{tr} \mathbf{Q}_B(\mathbf{Q}_B + \mathbf{Q}_e)^{-1}$ are asymptotically distributed according to a chi-square distribution with pm degrees of freedom under the null hypothesis. Even under the alternative hypothesis that the matrix of noncentrality parameters $\Omega = o(1)$ for large n , the asymptotic distributions remain the same. When $\Omega = O(1)$, they are noncentral chi-square distributions of pm degrees of freedom and noncentrality parameter $\delta = \text{tr} \Omega$. If $\Omega = O(n)$, they are normal distributions, namely, $-\sqrt{n}(\log W + \log |I + \theta|)$, $\sqrt{n}(\text{tr} \mathbf{Q}_B \mathbf{Q}_e^{-1} - \text{tr} \theta)$ and $\sqrt{n}(\text{tr} \mathbf{Q}_B(\mathbf{Q}_B + \mathbf{Q}_e)^{-1} - \text{tr} \theta(I + \theta)^{-1})$ for $\theta = \lim \Omega/n$ have asymptotically normal distributions of zero means and variances given by $2 \text{tr}(I - (I + \theta)^{-2})$, $2 \text{tr}(2\theta + \theta^2)$, and

$2\text{tr}((I+\theta)^{-2}-(I+\theta)^{-4})$, respectively. As a special case, if $m=1$ there exists only one non-zero λ , and the procedures in this paragraph all coincide and are equivalent to one based on $T^2 = M^{-1}(\hat{\mathbf{B}} - B_0)' \hat{\Sigma}^{-1}(\hat{\mathbf{B}} - B_0)$. It is known that under the hypothesis, $(n-p)T^2/(n-1)p$ is distributed according to an F -distribution with $(p, n-p)$ degrees of freedom. When $p=2$ (resp. $m=2$), $(n-m-1)(1-\sqrt{W})/(m\sqrt{W})$ (resp. $(n-p-1)(1-\sqrt{W})/(p\sqrt{W})$) is distributed according to an F -distribution with degrees of freedom $(2m, 2(n-m-1))$ (resp. $(2p, 2(n-p-1))$). Simultaneous \dagger confidence regions of B can be derived from the testing procedures in this paragraph, that is,

$$\text{tr} \mathbf{Q}_e^{-1}(B - \hat{\mathbf{B}})ZZ'(B - \hat{\mathbf{B}})' < c.$$

Moreover, when the matrix B is decomposed as $B = (B_1; B_2)$, where B_1 and B_2 are a $p \times q$ matrix and a $p \times (m-q)$ matrix, respectively, and the hypothesis to be tested is of the form $B_1 = 0$, the test procedures can be obtained as follows: Decompose Z as

$$Z = \begin{pmatrix} Z_1 \\ Z_2 \end{pmatrix},$$

where Z_1 is a $q \times n$ matrix and Z_2 is an $(m-q) \times n$ matrix, and put

$$\hat{\mathbf{B}}_2^* = \mathbf{X}Z_2'(Z_2Z_2')^{-1},$$

$$\mathbf{Q}^* = \mathbf{X}\mathbf{X}' - \hat{\mathbf{B}}_2^*Z_2'\mathbf{X}', \quad \mathbf{Q}_{B_1} = \mathbf{Q}^* - \mathbf{Q}_e.$$

Then \mathbf{Q}_{B_1} and \mathbf{Q}_e are independent, \mathbf{Q}_{B_1} is distributed according to a Wishart distribution with q degrees of freedom when the hypothesis is true, and we can apply the procedures in the previous paragraph, simply replacing \mathbf{Q}_B by \mathbf{Q}_{B_1} .

Such a procedure is called **multivariate analysis of variance** (or **MANOVA**, for short). Various standard situations can be treated in this way (after some linear transformation of variables, if necessary). Some examples are (1) $\mathbf{X} = (\mathbf{X}^{(1)} \dots \mathbf{X}^{(n)})$, where the $\mathbf{X}^{(i)}$ ($i=1, \dots, n$) are distributed independently according to a p -dimensional normal distribution $N(\boldsymbol{\mu}, \Sigma)$. We can express \mathbf{X} as $\mathbf{X} = \boldsymbol{\mu}\mathbf{1}' + \mathbf{U}$, and the estimators are given by $\hat{\boldsymbol{\mu}} = \bar{\mathbf{X}} = \mathbf{X}\mathbf{1}/n$, $\hat{\Sigma} = (\mathbf{X} - \bar{\mathbf{X}}\mathbf{1}')(\mathbf{X} - \bar{\mathbf{X}}\mathbf{1}')'/(n-1)$. In this case, we obtain a test for the hypothesis $\boldsymbol{\mu} = \boldsymbol{\mu}_0$ based on **Hotelling's** T^2 statistic, i.e., the test with a \dagger critical region of the form

$$T^2 = n(\bar{\mathbf{X}} - \boldsymbol{\mu}_0)' \hat{\Sigma}^{-1}(\bar{\mathbf{X}} - \boldsymbol{\mu}_0) > c.$$

(2) Suppose that $p \times n_i$ matrices \mathbf{X}_i , $i=1, \dots, k$, are samples of size n_i from p -dimensional normal distributions $N(\boldsymbol{\mu}_i, \Sigma)$ with common covariance matrix Σ . The tests for the hypothesis $\boldsymbol{\mu}_1 = \dots = \boldsymbol{\mu}_k$ are obtained from the following observation: Let $\mathbf{Q}_e = \sum_i (\mathbf{X}_i - \bar{\mathbf{X}}_i\mathbf{1}')(\mathbf{X}_i - \bar{\mathbf{X}}_i\mathbf{1})'$, where $\bar{\mathbf{X}}_i = \mathbf{X}_i\mathbf{1}/n_i$, $\mathbf{Q}_\mu = \sum n_i(\bar{\mathbf{X}}_i - \bar{\mathbf{X}})$

$(\bar{\mathbf{X}}_i - \bar{\mathbf{X}})'$, $\bar{\mathbf{X}} = \sum n_i \bar{\mathbf{X}}_i / \sum n_i$. Then $\sum (\mathbf{X}_i - \bar{\mathbf{X}}\mathbf{1}')(\mathbf{X}_i - \bar{\mathbf{X}}\mathbf{1})' = \mathbf{Q}_\mu + \mathbf{Q}_e$. We call \mathbf{Q}_e the **matrix of the sum of squares within classes**, and \mathbf{Q}_μ the **matrix of the sum of squares between classes**.

The latter is distributed according to a Wishart distribution when the hypothesis is true.

(3) Suppose that \mathbf{X}_{ij} are p -dimensional vectors, and that

$$\mathbf{X}_{ij} = \boldsymbol{\mu} + \boldsymbol{\alpha}_i + \boldsymbol{\beta}_j + \mathbf{U}_{ij}, \quad \begin{matrix} i=1, \dots, m, \\ j=1, \dots, n, \end{matrix}$$

where $\boldsymbol{\mu}$, $\boldsymbol{\alpha}_i$, $\boldsymbol{\beta}_j$ are p -dimensional constant vectors such that $\sum \boldsymbol{\alpha}_i = 0$ and $\sum \boldsymbol{\beta}_j = 0$, and the \mathbf{U}_{ij} are independently distributed according to a p -dimensional normal distribution $N(0, \Sigma)$.

We set

$$\mathbf{Q}_\alpha = n \sum (\bar{\mathbf{X}}_{i.} - \bar{\mathbf{X}})(\bar{\mathbf{X}}_{i.} - \bar{\mathbf{X}})',$$

$$\mathbf{Q}_\beta = m \sum (\bar{\mathbf{X}}_{.j} - \bar{\mathbf{X}})(\bar{\mathbf{X}}_{.j} - \bar{\mathbf{X}})',$$

$$\mathbf{Q}_e = \sum \sum (\mathbf{X}_{ij} - \bar{\mathbf{X}}_{i.} - \bar{\mathbf{X}}_{.j} + \bar{\mathbf{X}}) \times (\mathbf{X}_{ij} - \bar{\mathbf{X}}_{i.} - \bar{\mathbf{X}}_{.j} + \bar{\mathbf{X}})',$$

where

$$\bar{\mathbf{X}}_{i.} = \sum_j \mathbf{X}_{ij}/n, \quad \bar{\mathbf{X}}_{.j} = \sum_i \mathbf{X}_{ij}/m,$$

$$\bar{\mathbf{X}} = \sum \sum \mathbf{X}_{ij}/mn.$$

Then we have $\sum \sum (\mathbf{X}_{ij} - \bar{\mathbf{X}})(\mathbf{X}_{ij} - \bar{\mathbf{X}})' = \mathbf{Q}_\alpha + \mathbf{Q}_\beta + \mathbf{Q}_e$, and \mathbf{Q}_α , \mathbf{Q}_β , \mathbf{Q}_e are distributed independently according to (noncentral) Wishart distributions with degrees of freedom $m-1$, $n-1$, and $(n-1)(m-1)$, respectively. The tests for the hypothesis $\boldsymbol{\alpha}_i = 0$ ($i=1, \dots, m$) or $\boldsymbol{\beta}_j = 0$ ($j=1, \dots, n$) are obtained from these matrices.

C. Tests for Covariance Matrices

Let \mathbf{X}_{ij} ($p \times 1$), $j=1, \dots, N_i$, be a random sample from p -variate normal distribution $N(\boldsymbol{\mu}_i, \Sigma_i)$ for $i=1, \dots, k$. For testing the hypothesis $H_0: \Sigma_1 = \dots = \Sigma_k$ with unknown mean vectors $\boldsymbol{\mu}_i$ against all alternatives, the likelihood ratio statistic is given by

$$\frac{N^{N/2} \prod_i |\mathbf{S}_i|^{N_i/2}}{\prod_i N_i^{N_i/2} |\sum \mathbf{S}_i|^{N/2}}, \quad N = N_1 + \dots + N_k, \quad (2)$$

where $\mathbf{S}_i = \sum_{j=1}^{N_i} (\mathbf{X}_{ij} - \bar{\mathbf{X}}_i)(\mathbf{X}_{ij} - \bar{\mathbf{X}}_i)'$ for $\bar{\mathbf{X}}_i = \sum_{j=1}^{N_i} \mathbf{X}_{ij}/N_i$. If we replace the sample size N_i by the degrees of freedom $n_i = N_i - 1$ and N by $n = N - k$ in (2), the modified likelihood ratio test is unbiased for general p and k [16]. For $k=1$, the hypothesis specifies $H_0: \Sigma_1 = \Sigma_0$ (a given positive definite matrix) and the likelihood ratio statistic is given by $|S|^{N/2} \text{etr}(-\Sigma_0^{-1} S/2)$ ($\text{etr}(x) = \exp(\text{tr } x)$). Again replacing N by $n = N - 1$ yields an unbiased test. Moreover the power function of this modified likelihood ratio test depends only on the eigenvalues of $\Sigma_1 \Sigma_0^{-1}$ and is increasing with respect to the absolute deviation of each

eigenvalue from 1, that is, $|ch_i \Sigma_1 \Sigma_0^{-1} - 1|$. For $k=2$, it is conjectured that the modified likelihood ratio test has a power function monotonically increasing with respect to $|ch_i \Sigma_1 \Sigma_2^{-1} - 1|$. This conjecture has not yet been proved; we know only that the power is increasing if the maximum eigenvalue $ch_1 \Sigma_1 \Sigma_2^{-1}$ increases from 1 or the minimum eigenvalue $ch_p \Sigma_1 \Sigma_2^{-1}$ decreases from 1.

D. Estimation of Mean Vector and Covariance Matrix

Let $\mathbf{X}(p \times 1)$ have p -variate normal distribution $N(\boldsymbol{\mu}, I)$. For estimating the unknown mean, take the sum of squared errors S as a loss $L(\boldsymbol{\mu}, d) = \|\boldsymbol{\mu} - d\|^2$. Since each component X_i of \mathbf{X} is distributed independently according to $N(\mu_i, 1)$ for $\boldsymbol{\mu} = (\mu_1, \dots, \mu_p)'$, it is natural to suppose that \mathbf{X} is a good estimator. In fact \mathbf{X} is a minimax estimator for $\boldsymbol{\mu}$. However, Stein showed that \mathbf{X} is admissible for $p=1$ and 2 but inadmissible for $p \geq 3$. James and Stein showed that the estimator

$$\left(1 - \frac{p-2}{\|\mathbf{X}\|^2}\right)\mathbf{X} \quad (3)$$

dominates \mathbf{X} when $p \geq 3$. This estimator is further dominated by Stein's positive part estimator $(1 - (p-2)/\|\mathbf{X}\|^2)_+ \mathbf{X}$, where $(a)_+$ means a if a is nonnegative and zero if a is negative. The class of estimators $\mathbf{X} + \nabla \log f(\mathbf{X})$, where $\nabla = (\partial/\partial x_1, \dots, \partial/\partial x_p)'$ for $\mathbf{X}' = (x_1, \dots, x_p)$ are all minimax for $\boldsymbol{\mu}$ dominating \mathbf{X} , if $f(\mathbf{X}) \geq 0$ and $\sqrt{f(\mathbf{X})}$ is superharmonic ($\nabla^2 \sqrt{f(\mathbf{X})} \leq 0$), satisfying $E[\|\nabla \log f(\mathbf{X})\|^2] < \infty$ and $E[\Sigma(\partial^2 f(\mathbf{X})/\partial x_i^2)/f(\mathbf{X})] < \infty$. Putting $f(\mathbf{X}) = \|\mathbf{X}\|^{-(p-2)}$ yields the James-Stein estimator (3). For this problem a class of monotone estimators is essentially complete, where an estimator $d(\mathbf{X})$ is called monotone if $d(\mathbf{X}) \leq d(\mathbf{Y})$ whenever $\mathbf{X} \leq \mathbf{Y}$ (defined componentwise). Stein's positive-part estimator is not monotone and is still inadmissible [8].

Let $\mathbf{X}_i(p \times 1)$, $i=1, \dots, n$, be a random sample taken from the p -variate normal distribution $N(\mathbf{0}, \Sigma)$. Then the maximum likelihood estimator for Σ is given by S/n , where $S = \sum_{i=1}^n \mathbf{X}_i \mathbf{X}_i'$. S has Wishart distribution $W_p(n, \Sigma)$. To study the estimation problem of Σ , take two loss functions $L_1(\Sigma, d) = \text{tr } d \Sigma^{-1} - \log |d \Sigma^{-1}| - p$ and $L_2(\Sigma, d) = (1/2) \text{tr}(d \Sigma^{-1} - I)^2$. Under L_1 -loss, the best scalar multiple of S is given by S/n , and under L_2 -loss it is given by $S/(n+p+1)$. The James-Stein minimax estimator for L_1 -loss is given by $d_1(S) = K \Delta K'$, where K is the lower triangular matrix with positive diagonal element for which $S = K K'$ and $\Delta = \text{diag}(\Delta_1, \dots, \Delta_p)$ with $\Delta_i = 1/(n+p+1-2i)$. A minimax estimator for

L_2 -loss is given by $d_2(S) = K \Delta K'$ with the same lower triangular matrix K , but Δ is the solution of the linear equation $A \Delta = b$, where A is given by

$$A = \begin{bmatrix} (n+p-1)(n+p+1) & n+p-3 & & & \\ n+p+3 & (n+p-3)(n+p-1) & & & \\ \dots & \dots & \dots & \dots & \\ n-p+1 & n-p+1 & & & \\ & \dots & n-p+1 & & \\ & \dots & n-p+1 & & \\ & \dots & \dots & \dots & \\ & \dots & (n-p+1)(n-p+3) & & \end{bmatrix}$$

and $b' = (n+p-1, n+p-3, \dots, n-p+1)$. The minimax estimators $d_1(S)$ and $d_2(S)$ dominate the best scalar multiples of S . However, they are inadmissible. Let P be a permutation matrix, then the estimator $\Sigma_p P' d_i(PSP')P/p!$ dominates $d_i(S)$ because of the convexity of the loss function L_i for $i=1$ and 2. The estimator $h_1(S) = (S + ub(u)C)/n$, where $u = 1/\text{tr } CS^{-1}$ and C is a fixed positive-definite matrix, dominates S/n under L_1 -loss if $0 \leq b(u) \leq 2(p-1)/n$ and $b(\cdot)$ is nonincreasing. Under L_2 -loss $(S + bC/\text{tr } CS^{-1})/(n+p+1)$ dominates $S/(n+p+1)$, if $0 \leq b \leq 2(p-1)/(n-p+3)$ [7]. The Haff estimator $h_1(S)$ is dominated by the James-Stein estimator $d_1(S)$ if $p \geq 6$. The estimators $(S + b(\text{tr } CS^{-1}/\text{tr } CS^{-2})C)/n$ for $0 \leq b \leq 2(p-1)/n$ under L_1 -loss also dominate S/n and are not dominated by $d_1(S)$. Similar results hold under L_2 -loss.

E. Correlation among Variables

In order to represent the interrelationships among the p variates, the population correlation matrix $P = \{\rho_{ij}\}$ is used. Also, we can calculate the population \dagger multiple correlation coefficient of the i th component X_i and all the rest of the variables by

$$\rho_{i:1\dots(i)\dots p} = \sqrt{1 - P/P_{ii}},$$

and the \dagger partial correlation coefficient of X_i and X_j , given all others, by

$$\rho_{ij:1\dots(i)\dots(j)\dots p} = -P_{ij}/\sqrt{P_{ii}P_{jj}},$$

where P_{ij} are the cofactors of P (\rightarrow 397 Statistical Data Analysis).

The sample correlation matrix is calculated from the data, and the **sample multiple correlation** and the **sample partial correlation coefficients** are calculated from the sample correlation matrix in exactly the same way as the population coefficients are calculated from the population correlation matrix. When $\mathbf{X} = (\mathbf{X}^{(1)} \dots \mathbf{X}^{(n)})$ is a sample of size n from a multivariate normal population, the sampling distributions of $R_{i:1\dots(i)\dots p}$ and $R_{ij:1\dots(i)\dots(j)\dots p}$ are known (\rightarrow 374 Sampling Distributions).

The determinant of the covariance matrix $|\Sigma|$ (or $|\mathbf{S}|$), called the **(sample) generalized variance**, is a measure of the dispersion of a p -dimensional distribution. The distance of two distributions with mean vectors μ_1 and μ_2 , respectively, and with common variance Σ is often expressed by

$$\delta = (\mu_1 - \mu_2)' \Sigma^{-1} (\mu_1 - \mu_2),$$

which is called the **Mahalanobis generalized distance**.

When the data consists of $(p+q)$ -dimensional vectors $\begin{pmatrix} \mathbf{X} \\ \mathbf{Y} \end{pmatrix}$ with $q < p$, the interrelation of \mathbf{X} and \mathbf{Y} as a whole can be expressed in the following way: Let the covariance matrix be partitioned as

$$\Sigma = \begin{pmatrix} \Sigma_{XX} & \Sigma_{YX} \\ \Sigma_{XY} & \Sigma_{YY} \end{pmatrix}$$

and the nonzero roots of the equation $|\rho \Sigma_{YY} - \Sigma_{YX} \Sigma_{XX}^{-1} \Sigma_{XY}| = 0$ be ρ_1, \dots, ρ_q . Then $\rho_1^{1/2}, \dots, \rho_q^{1/2}$, called the **canonical correlation coefficients**, are the maximal invariant parameters with respect to linear transformation of \mathbf{X} and \mathbf{Y} . Also, if we denote the eigenvector corresponding to a root ρ_i by η_i , i.e.,

$$(\rho_i \Sigma_{YY}) \eta_i = (\Sigma_{YX} \Sigma_{XX}^{-1} \Sigma_{XY}) \eta_i,$$

the linear function $\eta_i' \mathbf{Y}$ and $\eta_i' \Sigma_{YX} \Sigma_{XX}^{-1} \mathbf{X}$ are called the **canonical variates**.

F. Principal Components

An important problem in multivariate analysis is to express the variations of many variables by a small number of indices. **Principal component analysis** is a technique of dealing with this problem.

Let \mathbf{X} be a $p \times n$ matrix with n column vectors of p -dimensional data. A linear transform of \mathbf{X} , $\mathbf{T} = \mathbf{A}\mathbf{X}$ (\mathbf{A} an $r \times p$ matrix, $r < p$, \mathbf{T} an $r \times n$ matrix) is called the **principal component** if \mathbf{A} is chosen so as to maximize the sum of the squares of the sample multiple correlation coefficients of each of the row vectors of \mathbf{X} to those of \mathbf{T} , namely, if \mathbf{A} is an $r \times p$ matrix formed by the r eigenvectors of the sample correlation matrix of \mathbf{X} corresponding to the r largest eigenvalues or any nonsingular linear transformation of them. This is a characterization of principal components in terms of correlation optimality.

The principal component $\mathbf{T} = \mathbf{A}\mathbf{X}$ is also characterized by the information-loss optimality in that all eigenvalues of $(\mathbf{X} - \mathbf{C}\mathbf{Y} - \mathbf{b}\mathbf{1}_n)'(\mathbf{X} - \mathbf{C}\mathbf{Y} - \mathbf{b}\mathbf{1}_n)$ are simultaneously minimized subject to the condition: \mathbf{C} is a $p \times r$ matrix, \mathbf{b} is a $p \times 1$ vector and \mathbf{Y} is an $r \times n$ matrix. The solution is given by $\mathbf{C}\mathbf{Y} + \mathbf{b}\mathbf{1}_n' = \mathbf{A}'\mathbf{T} + \bar{\mathbf{x}}\mathbf{1}_n'$,

where $\bar{\mathbf{x}} = \mathbf{X}\mathbf{1}_n/n$. The variation optimality of the principal component is given by maximizing simultaneously all the eigenvalues of the matrix $\mathbf{C}'(\mathbf{X} - \bar{\mathbf{x}}\mathbf{1}_n')(\mathbf{X} - \bar{\mathbf{x}}\mathbf{1}_n')\mathbf{C}$, subject to the condition that \mathbf{C} is a $p \times r$ matrix such that $\mathbf{C}'\mathbf{C} = \mathbf{I}_r$. The solution is given by $\mathbf{C} = \mathbf{A}'$, namely, $\mathbf{C}'\mathbf{X} = \mathbf{T}$ [15]. If all the correlations between the components of \mathbf{X} are positive, the largest eigenvalue of the covariance matrix of \mathbf{X} is simple and positive. All the coefficients of the first principal component (components of the eigenvector) can be taken to be positive (Perron-Frobenius theorem).

When we assume normality, the eigenvalues of the sample correlation matrix \mathbf{R} are the maximum likelihood estimators of the eigenvalues of the population correlation matrix, and their sampling distributions can be obtained. A hypothesis relevant to principal component analysis is, for example, that the smallest $p-r$ eigenvalues of the correlation matrix are equal, which can be tested by the statistic

$$R_{p-r} = |\mathbf{R}| / (\lambda_1 \dots \lambda_r ((p - \lambda_1 - \dots - \lambda_r) / (p - r))^{p-r}),$$

where $\lambda_1, \dots, \lambda_r$ are the r largest eigenvalues of \mathbf{R} . Under the hypothesis, $-\log R_{p-r}$ (a constant) is asymptotically distributed according to a chi-square distribution when $n \rightarrow \infty$.

Variations of principal component analysis can be obtained by taking the eigenvectors of the covariance matrix of the raw data or of a multiple of it by some weight matrix.

G. Factor Analysis

Factor analysis is closely related to principal component analysis. We assume a model

$$\mathbf{X} = \mathbf{B}\mathbf{F} + \mathbf{U},$$

where \mathbf{B} and \mathbf{F} are unknown $p \times r$ and $r \times n$ matrices of constants ($p > r$) and \mathbf{U} is a $p \times n$ matrix of independent errors. \mathbf{F} is called the matrix of **factor scores** and \mathbf{B} the matrix of **factor loadings**. We assume $\mathbf{F}\mathbf{F}' = n\mathbf{I}$. If $\mathbf{E}(\mathbf{U}\mathbf{U}') = n\Phi$ is known, then by applying the least squares principle, we can determine \mathbf{B} and \mathbf{F} so as to minimize the trace of $(\mathbf{X} - \mathbf{B}\mathbf{F})\Phi^{-1}(\mathbf{X} - \mathbf{B}\mathbf{F})$. Then \mathbf{B} is obtained by taking the r eigenvectors of $\Phi^{-1}\mathbf{X}\mathbf{X}'$ corresponding to the r largest eigenvalues. When Φ is diagonal but unknown, we can solve the simultaneous equation for \mathbf{B} and Φ , whose solutions are the matrix $\hat{\mathbf{B}}$ with columns equal to eigenvectors of $\hat{\Phi}^{-1}\mathbf{X}\mathbf{X}'$ and the diagonal matrix $\hat{\Phi}$ with elements equal to the diagonal elements of $\mathbf{X}\mathbf{X}'/n - \hat{\mathbf{B}}\hat{\mathbf{B}}'$.

If we assume that \mathbf{U} is normal, the procedure in the preceding paragraph for the case

when Φ is known is equivalent to the maximum likelihood method. When Φ is unknown, we can assume further that the columns in F are also multivariate normal vectors distributed independently of U , which implies that the columns of X are also normal vectors with the covariance matrix $\Sigma = BB' + \Phi$. B and Φ are estimated from the sample covariance matrix, and the solutions of the simultaneous equation for B and Φ gives the maximum likelihood estimators. However, there is the so-called **identification** problem of determining whether for given Σ and r the decomposition $\Sigma = BB' + \Phi$ is unique. This problem has not yet been completely settled. If the solution $\hat{\Phi}$ is positive definite and $\hat{B}\hat{B}'$ is positive semidefinite, it is called proper. When Φ is not positive definite, it is called a Haywood case, and when $\hat{B}\hat{B}'$ is not positive semidefinite it is called a complex case. Sometimes iterative procedures lead to improper solutions.

H. Canonical Correlation Analysis

Canonical correlation analysis can also be used for descriptive purposes. Sample canonical variates have various descriptive implications. Suppose that $\eta'_1 Y$ and $\xi'_1 X$ are the first canonical variates corresponding to the largest canonical correlation $\rho_1^{1/2}$. Then $\rho_1^{1/2}$ is the largest possible correlation between a linear function of X and a linear function of Y and is actually equal to the correlation of $\eta'_1 Y$ and $\xi'_1 X$. Similarly, the second canonical correlation is equal to the largest possible correlation between linear functions in X and in Y which are orthogonal to $\xi'_1 X$ and $\eta'_1 Y$, respectively, and so forth.

As a second interpretation of the canonical variates, we consider the linear regression model

$$Y = BX + U,$$

where Y , B , U are $q \times n$, $q \times p$, $q \times n$ matrices, respectively, and rank $B = r < q$. Then there exist an $r \times p$ matrix A and a $q \times r$ matrix C satisfying $C'\Sigma^{-1}C = I$ such that $B = CA$, where $E(UU') = n\Sigma$. Putting $T = AX$, we get a regression model $Y = CT + U$, regarding T as a matrix of regressor variables. If Σ is known, least squares considerations lead to minimizing $\text{tr}(Y - BX)' \Sigma^{-1} (Y - BX)$ with the condition rank $B = r$. The resulting row vectors of A consist of the r eigenvectors corresponding to the r largest eigenvalues of the matrix $S_{xx}^{-1} S_{xy} \Sigma^{-1} S_{yx}$ and column vectors of C consist of the r eigenvectors corresponding to the r largest eigenvalues of the matrix $S_{yx} S_{xx}^{-1} S_{xy} \Sigma^{-1}$. If Σ is replaced by S_{yy} , $T = AX$ and $Z = C'S_{yy}^{-1} Y$ are equal to the matrices of canonical variates.

If we assume that U is normal, this procedure is equivalent to the maximum likelihood method. It should be remarked that although the model here is not symmetric in X and Y , the results are symmetric in X and Y , and therefore they will be the same if the roles of X and Y are interchanged in this model.

I. Linear Discriminants and Problems of Classification

Let $p \times n_i$ matrices X_i ($i = 1, \dots, k$) be the set of observations for k distinct populations with a common covariance matrix. We determine a vector a such that $T_i = a'X_i$ reveals the differences of the k populations as much as possible, or, more precisely, so that the ratio of the sum of squares between classes of T to the sum of squares within classes is maximized. If the matrices of the sums of squares between and within classes are Q_b and Q_w , respectively, the ratio is equal to

$$l = a'Q_b a / a'Q_w a,$$

which is maximized when a is equal to the eigenvector of $Q_w^{-1}Q_b$ corresponding to the largest eigenvalue. The linear function $t = a'X$ is called the **linear discriminant function**. When $k = 2$, a is given by $a = Q_w^{-1}(\bar{X}_1 - \bar{X}_2)$, where \bar{X}_1 and \bar{X}_2 are sample mean vectors. When $k > 2$, we let A be the matrix formed by the r eigenvectors corresponding to the first r largest eigenvalues of $Q_w^{-1}Q_b$, and set $T_i = AX_i$. From this we can construct the r -dimensional discriminant function. These functions can be used to locate the k populations in r -dimensional space, and also to decide to which population a new observation belongs. For the latter problem we can also construct k quadratic functions $s_i = (X - \bar{X}_i)'Q_w^{-1}(X - \bar{X}_i)$, where \bar{X}_i is the sample mean vector of the i th population, and X a new observation. Then we can decide whether X belongs to the population corresponding to the minimum s_i . Such a method is called a **classification procedure**.

J. Discrete Multivariate Analysis

Let X_{ijk} be an observed frequency on three characteristics, each belonging to ijk th class for $1 \leq i \leq I$, $1 \leq j \leq J$ and $1 \leq k \leq K$. Assume that X_{ijk} is a sample from multinomial distribution having p_{ijk} as a probability of occurrence for an (i, j, k) cell, where $p_{...} = \sum p_{ijk} = 1$. The multinomial observation X_{ijk} with probability p_{ijk} is called an $I \times J \times K$ contingency table. If we further assume that

$$\log p_{ijk} = \mu + \alpha_i + \beta_j + \gamma_k + \alpha_{ij} + \beta_{jk} + \gamma_{ki} + \delta_{ijk}$$

with the restrictions on parameters $\sum_i \alpha_i = \sum_i \alpha_{ij} = \sum_j \alpha_{ij} = 0$, similarly on β 's and γ 's and $\sum_i \delta_{ijk} = \sum_j \delta_{ijk} = \sum_k \delta_{ijk} = 0$, we say that a saturated log-linear model is given. Here the number of observations and the number of parameters are equal, and no errors can be estimated. The parameter δ_{ijk} is called the three-factor effect, or equivalently, the second-order interaction. Similarly, α_{ij} , β_{jk} , γ_{ki} are called the two-factor effects or the first-order interactions. Finally α_i , β_j , γ_k are called the main effects. A simple model is obtained when all the first- and second-order interactions vanish. This is equivalent to the independence model: $p_{ijk} = p_{i..} p_{.j.} p_{.k.}$ and the maximum likelihood estimators for μ , α_i , β_j , γ_k are obtained from $\hat{p}_{ijk} = \mathbf{X}_{i.} \mathbf{X}_{.j.} \mathbf{X}_{.k.} / n^3$, where $n = \mathbf{X}_{...}$. A nontrivial model is obtained by putting all the second-order interactions equal to zero. The likelihood equations for this model are given by

$$np_{ij.} = \mathbf{X}_{ij.}, \quad np_{i.k} = \mathbf{X}_{i.k}, \quad np_{.jk} = \mathbf{X}_{.jk}. \tag{4}$$

Bartlett first described a solution of (4) when $I = J = K = 2$. For a $2 \times 2 \times 2$ table, the solution can be expressed by $\hat{p}_{ijk} = (x_{ijk} \pm \theta) / n$ because of the constraints for $\mathbf{X}_{ij.}$, $\mathbf{X}_{i.k}$, and $\mathbf{X}_{.jk}$. Putting $\delta_{111} = \theta$ for \hat{p}_{ijk} yields a cubic equation for θ :

$$\begin{aligned} &(\mathbf{X}_{111} + \theta)(\mathbf{X}_{122} + \theta)(\mathbf{X}_{221} + \theta)(\mathbf{X}_{212} + \theta) \\ &= (\mathbf{X}_{121} - \theta)(\mathbf{X}_{112} - \theta)(\mathbf{X}_{211} - \theta)(\mathbf{X}_{222} - \theta). \end{aligned}$$

For a general $I \times J \times K$ table, the equations (4) have a unique solution within the no-three-factor effect model if there exists $q_{ijk} > 0$ satisfying (4). The unique solution maximizes the likelihood. To solve the likelihood equations (4), standard iterative procedures, such as the Newton-Raphson method, can be applied. However, the following iterative scaling method of Deming and Stephan is more useful:

$$\begin{aligned} np_{ijk}^{(3m+1)} &= p_{ijk}^{(3m)} \frac{\mathbf{X}_{ij.}}{p_{ij.}^{(3m)}}, \\ np_{ijk}^{(3m+2)} &= p_{ijk}^{(3m+1)} \frac{\mathbf{X}_{i.k}}{p_{i.k}^{(3m+1)}}, \\ np_{ijk}^{(3m+3)} &= p_{ijk}^{(3m+2)} \frac{\mathbf{X}_{.jk}}{p_{.jk}^{(3m+2)}}. \end{aligned} \tag{5}$$

The first iteration adjusts $p_{ijk}^{(3m)}$ by fitting proportionally with respect to k so that $np_{ij.}^{(3m+1)}$ is equal to $\mathbf{X}_{ij.}$, and similarly for the second and third iterations. Starting with any initial values satisfying the first-order interaction model, the iterative scaling method (5) converges to the unique solution of (4) as $m \rightarrow \infty$.

K. Other Problems

The sampling distributions associated with the procedures discussed here are usually very

complicated, and often only asymptotic properties are known (\rightarrow 374 Sampling Distributions). Nonparametric rank analogs of many multivariate techniques for normal distribution are found in [18]. Robustness of the distributions of test statistics or of latent roots is investigated in [3, 10, 14]. Multivariate data analysis is found in [5].

N

281 (XIX.5) Network Flow Problems

A. Introduction

The **network flow problem** is a special kind of mathematical-programming problem (\rightarrow 255 Linear Programming, 264 Mathematical Programming, 292 Nonlinear Programming), where the variables of the objective function and the constraints are all defined in terms of a graph (\rightarrow 186 Graph Theory). Owing to its special structure, the mathematical properties of the network flow problem as well as the solution algorithms have been investigated in detail. Network flow problems have a variety of useful applications in fields such as transportation, scheduling, and resource allocation, and in operations research in general, so that they now constitute an important class of mathematical programming. By the term "network" (*Netzwerk* in German, *réseau* in French, *сет'* in Russian) we usually mean a graph with some physical attributes attached to its edges and vertices.

B. Basic Form of the Problem

Let $G = (V, E, \delta^+, \delta^-)$ be a graph with vertex set V , edge set E , and incidence relations δ^+ , $\delta^-: E \rightarrow V$, and let \mathbf{R} be the field of real numbers. (Most of the statements in the following are valid if we take for \mathbf{R} an ordered field or ordered additive group more general than the field of real numbers.) Furthermore, we regard the collection Ξ of all functions $\xi: E \rightarrow \mathbf{R}$ as a vector space of dimension $|E|$, denoting $\xi(e_\kappa)$ by ξ^κ if $E = \{e_1, \dots, e_n\}$. Similarly, the collection Ω of all functions $\omega: V \rightarrow \mathbf{R}$ is a vector space of dimension $|V|$. If we define the mapping $\delta^\pm: V \rightarrow 2^E$ by $\delta^\pm v = \{e \mid \delta^\pm e = v\}$ (\rightarrow 186 Graph Theory), a linear mapping $\delta: \Xi \rightarrow \Omega$ is naturally introduced through the relation $(\delta\xi)(v) = \sum_{e \in \delta^+ v} \xi(e) - \sum_{e \in \delta^- v} \xi(e)$. A vector $\xi \in \Xi$ is called a **flow** on G if $\delta\xi = 0$. The dual space Ξ^* of Ξ and the dual Ω^* of Ω are identified with the collection of functions $\eta: E \rightarrow \mathbf{R}$ and that of $\zeta: V \rightarrow \mathbf{R}$, respectively, under the obvious correspondence. Then the linear mapping $\delta: \Omega^* \rightarrow \Xi^*$, which is contragredient to δ , is defined by means of the relation $(\delta\zeta)(e) = \zeta(\delta^+ e) - \zeta(\delta^- e)$. A vector $\eta \in \Xi^*$, which is the image of ζ under δ , i.e., which satisfies $\eta = \delta\zeta$, is called a **tension** on G , and ζ is called the **potential** on G corresponding to the tension η . (Sometimes, $\xi(e)$ is called a flow **in** edge e , $\eta(e)$ a tension **across** e , and $\zeta(v)$ a potential **at** vertex v .)

A continuous curve $C (\subset \mathbf{R} \times \mathbf{R})$ on the

Euclidean plane $\mathbf{R} \times \mathbf{R}$ is said to be **monotone** if $(x_1 - x_2)(y_1 - y_2) \geq 0$ for any $(x_1, y_1), (x_2, y_2) \in C$. A monotone curve C is called a **characteristic curve** if its projection to each coordinate axis, i.e., $C_x = \{x \mid (x, y) \in C\}$ and $C_y = \{y \mid (x, y) \in C\}$, is a closed interval. For a characteristic curve C , two convex functions, $\varphi(x) = \int_{x_0}^x (y - y_0) dx$ and $\psi(y) = \int_{y_0}^y (x - x_0) dy$, are defined, where (x_0, y_0) is a point fixed on C and the integrals are taken along $(x, y) \in C$. (It is understood that $\varphi(x) = \infty$ if $x \notin C_x$ and $\psi(y) = \infty$ if $y \notin C_y$.) These two functions defined for a fixed C are conjugate to each other in Fenchel's sense, and they satisfy $\varphi(x) + \psi(y) \geq (x - x_0)(y - y_0)$ for any $(x, y) \in \mathbf{R} \times \mathbf{R}$, where the inequality reduced to an equality if and only if $(x, y) \in C$ (\rightarrow 88 Convex Analysis, 292 Nonlinear Programming).

A network N in network flow theory is a graph G to each edge e_κ whose edge set $E = \{e_1, \dots, e_n\}$ is given a characteristic curve C^κ . On a network N , the following three problems, PI, PII, and PIII, are defined. PI: Find a flow ξ that minimizes $\Phi(\xi) \equiv \sum_{\kappa=1}^n \varphi_\kappa(\xi^\kappa)$ under the constraints $\xi^\kappa \equiv \xi(e_\kappa) \in C_x^\kappa$ ($\kappa = 1, \dots, n$). PII: Find a tension η which minimizes $\Psi(\eta) \equiv \sum_{\kappa=1}^n \varphi^\kappa(\eta_\kappa)$ under the constraints $\eta_\kappa \equiv \eta(e_\kappa) \in C_y^\kappa$ ($\kappa = 1, \dots, n$). PIII: Find a pair (ξ, η) of a flow ξ and a tension η such that $(\xi^\kappa, \eta_\kappa) \in C^\kappa$ for all $\kappa = 1, \dots, n$. (With respect to PI or PII, a flow or a tension satisfying the "constraints" is ordinarily called a **feasible** flow or tension, respectively.) Then, as a special case of the (Karush-)Kuhn-Tucker theorem and the duality theorem in nonlinear programming, we have the following theorems (A) and (B).

(A) For a given network N , one and only one of the following four alternatives is the case:

- (i) There is a feasible flow in PI, and at the same time, there is a feasible tension in PII. In this case, both PI and PII have a solution, and, for any solution $\hat{\xi}$ of PI and any solution $\hat{\eta}$ of PII, the pair $(\hat{\xi}, \hat{\eta})$ is a solution of PIII; and, conversely, for any solution $(\hat{\xi}, \hat{\eta})$ of PIII, the flow $\hat{\xi}$ is a solution of PI and the tension $\hat{\eta}$ is a solution of PII.
- (ii) There is a feasible tension in PII, whereas there is no feasible flow in PI. In this case, $\Phi(\xi)$ of PI is not bounded below for feasible tensions ξ .
- (iii) There is a feasible tension in PII, whereas there is no feasible flow in PI. In this case, $\Psi(\eta)$ of PII is not bounded below for feasible tensions η .
- (iv) There is neither a feasible flow in PI nor a feasible tension in PII.

(B) Let $C_x^\kappa = [b^\kappa, c^\kappa]$ ($b^\kappa \leq c^\kappa$; b^κ can be $-\infty$, and c^κ, ∞) and $C_y^\kappa = [d_\kappa, f_\kappa]$ (d_κ can be $-\infty$, and f_κ, ∞). Then a necessary and sufficient condition for PI to have a feasible flow is that

$\sum_1 c^k - \sum_2 b^k \geq 0$ for every cutset (cocycle or cocircuit) ω of G , where the summation \sum_1 (resp. \sum_2) is taken over all the edges e_k ($\in E$) that lie in ω in the positive (resp. negative) direction. Similarly, a necessary and sufficient condition for PII to have a feasible tension is that $\sum_1 f_k - \sum_2 d_k \geq 0$ for every tieset (cycle or circuit) θ of G , where \sum_1 (resp. \sum_2) is taken over all the edges e_k that lie in θ in the positive (resp. negative) direction.

C. Shortest Paths, Maximum Flows, and Minimum-Cost Flows

We choose one of the edges of G , say e_1 , as the **reference edge** and assign it the parametric characteristic curve $C^1 \langle \alpha \rangle = \{(x, y) | y = x + \alpha\}$. Then if there is a feasible flow on the network obtained from G by contracting (i.e., short-circuiting) e_1 , and if at the same time there is a feasible tension on the network obtained from G by deleting (i.e., open-circuiting) e_1 , then problem PIII has a solution $(\xi \langle \alpha \rangle, \eta \langle \alpha \rangle)$ for every real α , and $\xi^1 \langle \alpha \rangle$ and $\eta_1 \langle \alpha \rangle$ are uniquely determined for each α . The problem of determining these parametric solutions is the **two-terminal problem** for the **two-terminal network** N_1 (which is obtained from G by deleting e_1) with the vertex $\partial^- e_1$ as the **entrance** (or **source**) and the vertex $\partial^+ e_1$ as the **exit** (or **sink**). The curve $C = \{(\xi^1 \langle \alpha \rangle, \eta_1 \langle \alpha \rangle) | \alpha \in \mathbb{R}\}$ enjoys the properties of a characteristic curve, and is called the **two-terminal characteristic** of N_1 with respect to the entrance $\partial^- e_1$ and exit $\partial^+ e_1$. A two-terminal network for which only the projections to the x -axis $C_x^k = [b^k, c^k]$ of the edge characteristics are specified ($k = 2, \dots, n$) is called a **capacitated network**, and the **maximum-flow problem** for a capacitated network N_1 can be mathematically formulated as the problem of determining the projection to the x -axis $C_x = [b, c]$ of the two-terminal characteristics of N_1 . For the maximum-flow problem, the relation $c = \min\{\sum_1 c^k - \sum_2 b^k\}$ holds, where the minimum is taken over all the cutsets that contain e_1 in the negative direction and where \sum_1 (resp. \sum_2) denotes the summation over all the edges, except e_1 , lying in a cutset in the positive (resp. negative) direction. This relation is called the **maximum-flow minimum-cut theorem**. (A similar relation holds also for b .)

Similarly, or dually, the problem of determining the y -projection $C_y = [d, f]$ of the two-terminal characteristic of a two-terminal network N_1 for which the y -projections $C_y^k = [d_k, f_k]$ of the characteristics are specified to the nonreference edges e_k ($k = 2, \dots, n$) is a network flow formulation of the **shortest-path problem**. For the shortest-path problem, the

relation $f = \min\{\sum_1 f_k - \sum_2 d_k\}$, called the **maximum-separation minimum-distance theorem**, holds, where the minimum is taken over all the tiesets that contain e_1 in the positive direction and where \sum_1 (resp. \sum_2) denotes the summation over all the edges, except e_1 , lying in a tieset in the positive (resp. negative) direction.

The **minimum-cost flow problem** is to determine the two-terminal characteristic of N_1 when all the C^k ($k \neq 1$) are of staircase form.

A number of algorithms exist for time complexity (\rightarrow 71 Complexity of Computations) $O(|V|^3)$ for the shortest-path problem [4]; the algorithm proposed by E. W. Dijkstra [7] for the case $d_k \leq 0 \leq f_k$ for all k ($k \neq 1$) is of complexity $O(|V|^2)$. The algorithm of A. V. Karzanov [8, 9] for the maximum-flow problem is of complexity $O(|V|^3)$. The minimum-cost flow problem can be solved by alternately solving the subproblems of the shortest-path type and those of the maximum-flow type, but no algorithm of time complexity polynomial in $|E|$ and $|V|$ has been found.

D. Transportation and Scheduling

Let us make the edges of a graph $G = (V, E, \partial^+, \partial^-)$ correspond to the transportation routes and the flow to the stream of a commodity; impose a **capacity constraint** of the form $0 \leq \xi^k \leq c^k$ on the flow ξ^k in each edge e_k , and assume a **cost** function of the form $\varphi_k(\xi^k) = f_k \xi^k$ for each edge. (c^k is a constant called the **capacity** of edge e_k , and f_k is a constant called the **unit cost** of edge e_k .) Furthermore, let us specify a subset V_1 ($\subset V$) of vertices as the set of entrances and another subset V_2 ($\subset V$) as the set of exits, where $V_1 \cap V_2 = \emptyset$, and prescribe the amount of inflow $q(v)$ to each entrance $v \in V_1$ and the amount of outflow $q(v)$ from each exit $v \in V_2$, where we must have $\sum_{v \in V_1} q(v) = \sum_{v \in V_2} q(v)$. Planning a transportation plan that satisfies all the above-prescribed conditions and that minimizes the total cost $\sum_{k \in E} \varphi_k(\xi^k)$ can be reduced to finding a minimum-cost flow on the extended network $\tilde{G} = (\tilde{V}, \tilde{E}, \tilde{\partial}^+, \tilde{\partial}^-)$, defined as follows, such that the flow in the reference edge is to be maximum: $\tilde{V} = V \cup \{s\} \cup \{t\}$ ($s, t \notin V$), $\tilde{E} = E \cup E_1 \cup E_2 \cup \{e_0\}$ ($E_1 \cap E = E_2 \cap E = \emptyset$, $e_0 \notin E \cup E_1 \cup E_2$; e_0 is the reference edge, $\tilde{\partial}^+ e_0 = t$, $\tilde{\partial}^- e_0 = s$; $E_1 = \{e | \tilde{\partial}^+ e = s, \tilde{\partial}^- e = v, v \in V_1\}$, $C(e) = \{(0, y) | y \leq 0\} \cup \{(x, 0) | 0 \leq x \leq q(\tilde{\partial}^- e)\} \cup \{(q(v), y) | 0 \leq y\}$, where $\tilde{\partial}^- e = v \in V_1$; $E_2 = \{e | \tilde{\partial}^+ e = v, \tilde{\partial}^- e = t, v \in V_2\}$, $C(e) = \{(0, y) | y \leq 0\} \cup \{(x, 0) | 0 \leq x \leq q(v)\} \cup \{(q(v), y) | 0 \leq y\}$, where $\tilde{\partial}^+ e = v \in V_2$), $\tilde{\partial}^\pm |_E = \partial^\pm$, $C(e_k) = \{(0, y) | y \leq f_k\} \cup \{(x, f_k) | 0 \leq x \leq c^k\} \cup \{(c^k, y) | y \geq f_k\}$ for $e_k \in E$.

For the project-scheduling problem with an

Network Flow Problems

acyclic graph $G = (V, E, \delta^+, \delta^-)$ as the **arrow diagram** for which the **start node** $s \in V$ and the **completion node** are specified, we make an edge $e \in E$ correspond to a **job** (or **activity**), and a vertex correspond to the **event** that all the jobs corresponding to $\delta^- v$ have been finished, whereas those corresponding to $\delta^+ v$ are ready to commence. Then we interpret the negative of the tension of an edge as the time (i.e., duration) spent on the corresponding job and the potential at a vertex as the time (i.e., instant) of the corresponding event taking place. Furthermore, we assume that to each edge e_k (or the corresponding job) are given the **normal duration** $-d_k (> 0)$, the **crash duration** $-f_k (> 0, < -d_k)$, and the unit cost $c^k (> 0)$ we have to pay in order to decrease the job time by one unit, where the job time necessarily lies between the normal and the crash duration. Under the above-listed specifications, we consider the relation between the total project time (i.e., the duration from the event corresponding to the start node to that corresponding to the completion node) and the extra cost to be paid for decreasing the project time below the normal one. This problem can be reduced to the two-terminal characteristic problem for the following network \tilde{G} : \tilde{G} is obtained from G by adding the reference edge e_0 ($\tilde{\delta}^+ e_0 = t, \tilde{\delta}^- e_0 = s$); $C^* = \{(0, y) | y \leq d_k\} \cup \{(x, d_k) | 0 \leq x \leq c^k\} \cup \{(c^k, y) | d_k \leq y \leq f_k\} \cup \{(x, f_k) | c^k \leq x\}$.

E. Applications to Combinatorial Optimization

Many problems in combinatorial optimization can be reduced to network flow problems. The problem of finding a maximum matching on a bipartite graph G (\rightarrow 186 Graph Theory) is reduced to the maximum-flow problem for the graph representing the transportation problem on G with one of the two vertex sets as the entrance set and the other as the exit set, where all the edges have a unit capacity and the amount of inflow/outflow to/from each entrance/exit vertex is equal to unity (the cost being irrelevant). (The existence of an integer solution to this kind of maximum-flow problem is proved constructively on the basis of the solution algorithm.) The maximum-flow minimum-cut theorem in this particular case can be stated as follows: The maximum cardinality of matchings on a bipartite graph is equal to the minimum cardinality of vertex subsets which cover all the edges (this is known as the **König-Egerváry theorem**). The Dilworth theorem for a partially ordered set, the criterion for the existence of a graph with

prescribed vertex degrees, etc., are known to be reducible to network flow problems [2].

F. Generalizations

The network flow problem may be generalized in various directions. Replacing a graph by a matroid (\rightarrow 66 Combinatorics) or considering stronger conditions on the feasibility of flows and tensions are natural extensions [4, 6, 10, 11]. Another extension is to consider several kinds of flow, instead of a single kind, that simultaneously affect the capacities of edges. This latter problem is called the **multicommodity flow problem** in contrast to the **single-commodity flow problem** that was treated above [5]. It can be said that any extension of the network flow problem aims at a mathematical model that has wider application without losing the advantage of having simple effective solution algorithms.

282 (XX.17) Networks

A. Linear Graphs (\rightarrow 186 Graph Theory)

A **linear graph** (or simply **graph**) is an object composed of (i) a finite set $\{B_\kappa\}$ ($\kappa = 1, \dots, n$) of elements called **branches** (or **edges**), (ii) a finite set $\{N_a\}$ ($a = 1, \dots, m$) of elements called **nodes** (or **vertices**), and (iii) an **incidence relation** between branches and nodes represented by a function $[B_\kappa : N_a]$ from $\{B_\kappa\} \times \{N_a\}$ to $\{0, 1, -1\}$ such that for every κ , there exist exactly one N_a with $[B_\kappa : N_a] = 1$ and exactly one N_a with $[B_\kappa : N_a] = -1$, with all the other $[B_\kappa : N_a]$ equal to 0. (Intuitively, a branch B_κ starts from the node N_a with $[B_\kappa : N_a] = 1$ and ends at the node N_b with $[B_\kappa : N_b] = -1$.) In terms of topology, a (linear) graph is a 1-dimensional finite \dagger simplicial complex (\rightarrow 70 Complexes, 186 Graph Theory). A **network** in the wide sense is a linear graph whose branches and nodes are endowed with some physical properties.

B. Networks

A **contact network**, one of the simplest kinds of networks, is an abstraction of a circuit whose branches correspond to contact points of relays and switches that are allowed to take a finite number of physical states, e.g., the two states "on" and "off." The theory of contact networks is developed by means of \dagger Boolean algebra and is applied to switching networks, such as telephone exchange networks and the logical networks of digital computers.

In most cases, to the branches B_κ of a network two kinds of real quantities i_κ and E_κ are assigned (which may be variables or functions of time) satisfying the conditions:

$$(i) \sum_{\kappa=1}^n [B_\kappa : N_a] i_\kappa = 0 \quad (a = 1, \dots, m);$$

(ii) there exist E_a such that

$$\sum_{a=1}^m [B_\kappa : N_a] E_a = E_\kappa \quad (\kappa = 1, \dots, n).$$

In the case of **electric networks**, where i_κ , E_κ , and E_a are the current in branch B_κ , the voltage across branch B_κ , and the potential at node N_a , respectively, these conditions are known as **Kirchhoff's laws**.

The **network flow problem**, which has a number of practically important applications in \dagger operations research (e.g., transportation problems, project-scheduling problems) and is a special case of \dagger mathematical programming,

can be formulated as the problem of minimizing $\sum_{\kappa=1}^m f_\kappa(i_\kappa)$ under condition (i) (or minimizing $\sum_{\kappa=1}^n f_\kappa(E_\kappa)$ under condition (ii)), where for each branch B_κ , f_κ is a given \dagger convex function defined on a given interval $[a_\kappa, b_\kappa]$.

C. Electric Networks

Since there has been a great deal of research on electric networks, "network" often means "electric network." We call a branch in which the current is a given function of time a current source, and one across which the voltage is a given function of time a voltage source. A branch that is either a current source or a voltage source is called a **source branch**. A network with M source branches is called an **M-port network**. If the currents i_κ in and the voltages E_κ across the non-source branches (n' in number) are related by

$$E_\kappa = \sum_{\lambda=1}^{n'} z_{\kappa\lambda} i_\lambda \quad (\kappa = 1, \dots, n')$$

or

$$i_\kappa = \sum_{\lambda=1}^{n'} y_{\kappa\lambda} E_\lambda \quad (\kappa = 1, \dots, n'),$$

where the $z_{\kappa\lambda}$ or $y_{\kappa\lambda}$ are linear \dagger integrodifferential operators, the network is said to be **linear**. If $z_{\lambda\kappa} = z_{\kappa\lambda}$ or $y_{\kappa\lambda} = y_{\lambda\kappa}$, it is said to be **reciprocal** or **bilateral**; if the $z_{\kappa\lambda}$ or $y_{\kappa\lambda}$ are invariant under the change of the origin of time, it is said to be **time-invariant**; and if a linear time-invariant network satisfies the condition

$$\int_{-\infty}^t \sum_{B_\kappa \in S} i_\kappa(\tau) E_\kappa(\tau) d\tau \leq 0$$

for every t and for every choice of functions of time for i_κ or E_κ associated with the source branches B_κ in S , provided that the current-voltage relations for non-source branches are satisfied, then the network is said to be **passive**. Under certain nonsingularity conditions, for the currents in and the voltages across the source branches (denoted by I_κ and e_κ) of a linear M -port network, we have the relations

$$e_\kappa = \sum_{B_\lambda \in S} Z_{\kappa\lambda} I_\lambda, \quad I_\kappa = \sum_{B_\lambda \in S} Y_{\kappa\lambda} e_\lambda \quad (B_\kappa \in S),$$

where the matrices $Z_{\kappa\lambda}$ and $Y_{\kappa\lambda}$ of linear integrodifferential operators are called the **port-impedance matrix** and the **port-admittance matrix** of the network, respectively. **Analysis** determines $Z_{\kappa\lambda}$, $Y_{\kappa\lambda}$ from a given linear graph and given $z_{\kappa\lambda}$, $y_{\kappa\lambda}$, while **synthesis** finds a network (i.e., $z_{\kappa\lambda}$ or $y_{\kappa\lambda}$, as well as a linear graph) when part of $Z_{\kappa\lambda}$, $Y_{\kappa\lambda}$, or some relations to be satisfied by them are given. (In synthesis, the $z_{\kappa\lambda}$ or $y_{\kappa\lambda}$ are usually confined to some special class.) In analysis as well as synthesis we usu-

ally deal with the \dagger Laplace transforms $\bar{z}_{\kappa\lambda}(s)$, $\bar{y}_{\kappa\lambda}(s)$, $\bar{Z}_{\kappa\lambda}(s)$, $\bar{Y}_{\kappa\lambda}(s)$ instead of $z_{\kappa\lambda}$, $y_{\kappa\lambda}$, $Z_{\kappa\lambda}$, $Y_{\kappa\lambda}$ themselves, where the characteristics $Z_{\kappa\lambda}(s)$, $\bar{Y}_{\kappa\lambda}(s)$ of a network are determined by the topological properties of its linear graph and the properties of $\bar{z}_{\kappa\lambda}(s)$, $\bar{y}_{\kappa\lambda}(s)$ as functions of the complex variable s . (If ω is the angular frequency, $s = i\omega$.)

The following fundamental facts are known in regard to analysis and synthesis:

(1) If $\bar{Z}_{\kappa\lambda}(s)$, $\bar{Y}_{\kappa\lambda}(s)$ are rational functions of s holomorphic on the open right half-plane, a necessary and sufficient condition for a network to be passive is that for arbitrary real numbers ξ_{κ} ,

$$\sum_{B_{\kappa}, B_{\lambda} \in S} \xi_{\kappa} \xi_{\lambda} \bar{Z}_{\kappa\lambda}(s) \quad \text{or} \quad \sum_{B_{\kappa}, B_{\lambda} \in S} \xi_{\kappa} \xi_{\lambda} \bar{Y}_{\kappa\lambda}(s)$$

is a **positive real function** of s , i.e., a function whose value is real when s is real and lies on the right half-plane when s lies on the right half-plane.

(2) Every passive one-port network can be synthesized by using a finite number of three kinds of branches, i.e., positive resistors ($E_{\kappa} = R_{\kappa} i_{\kappa}$, $R_{\kappa} > 0$), positive capacitors ($i_{\kappa} = C_{\kappa} dE_{\kappa}/dt$, $C_{\kappa} > 0$), and positive inductors ($E_{\kappa} = L_{\kappa} di_{\kappa}/dt$, $L_{\kappa} > 0$).

(3) Every passive M -port network ($M \geq 2$) can be synthesized by using, in addition to the three kinds of branches mentioned in (2), ideal transformers (an ideal transformer is a pair of branches (B_{κ} , B_{λ}) such that $i_{\kappa} = n i_{\lambda}$, $E_{\lambda} = n E_{\kappa}$, and $n = \text{real number}$) and ideal gyrators (an ideal gyrator is a pair of branches (B_{κ} , B_{λ}) such that $i_{\kappa} = E_{\lambda}$, $i_{\lambda} = -E_{\kappa}$); ideal gyrators are not needed, however, to synthesize a reciprocal network.

However, very little is known about the synthesis of passive M -port networks without using ideal transformers and gyrators. Topological methods are expected to be powerful for such synthesis problems.

The linear graph structure of a network loses its significance if ideal transformers are admitted.

283 (XXI.37) Newton, Isaac

Sir Isaac Newton (December 25, 1642–March 20, 1727), the English mathematician and physicist, was born into a family of farmers in Woolsthorpe, Lincolnshire. In 1661, he entered Cambridge University, where he was greatly influenced by the professor who was teaching geometry, I. Barrow, and where he began research in Kepler's optics and Descartes's geometry.

In 1665, he discovered the \dagger binomial theorem, and in the same year, during a stay at his birthplace to escape the plague, he began work on his three great discoveries—the spectral decomposition of light, the universal law of gravity, and differential and integral calculus. He returned to Cambridge University in 1667, and in the following year invented the reflecting telescope and proposed his theory of light particles. During this period, he succeeded Barrow as professor and lectured on optics. At the same time, he probed deeper into the calculus. Guided by Barrow's insight that differentiation and integration were inverse operations and also by his own research on infinite series, Newton obtained the \dagger fundamental theorem of calculus. Leibniz obtained the same theorem a little later, and a struggle resulted between the two over priority. The two discoveries were independent, but because Leibniz's notation was superior, the later development of calculus owes more to him. The dynamic elucidation of the heliocentric theory was accomplished in Newton's main

work, *Principia mathematica philosophiae naturalis* (1686–1687), in which Kepler's law on the movement of the planets, Galileo's theory of movement, and Huygens's theory of oscillation were unified into the three laws of Newtonian dynamics. These natural laws, which deal with all dynamic phenomena in the universe, are the most superlative realization of Descartes's concept of exploring the mathematical structure of nature; they had an essential influence on the later development of the natural sciences. The style of writing is similar to that in Euclid's *Stoicheia*. In the *Principia*, Newton also sets forth his philosophical position.

In 1695, Newton moved to London and became engrossed in theology. He was appointed Master of the Mint and was president of the Royal Society from 1703 until his death. While he is sometimes said to have divorced himself from science, many of his notes on geometry date from this time.

284 (III.12) Noetherian Rings

A. General Remarks

In this article, we mean by ring a commutative ring with unity element. Thus a **Noetherian ring** is a commutative ring with unity element that satisfies the \dagger maximum condition for its ideals; if it is also an \dagger integral domain, then it is called a **Noetherian integral domain** or **Noetherian domain** (for right and left Noetherian rings \rightarrow 368 Rings F).

A ring is Noetherian if and only if every prime ideal of the ring has a \dagger finite basis (**Cohen's theorem**). A ring is Noetherian if it is

generated by a finite number of elements over a Noetherian ring (**Hilbert's basis theorem**). The following three conditions for a ring R are equivalent: (i) R is an **Artinian ring**, that is, it satisfies the \dagger minimum condition for its ideals (for right and left Artinian rings \rightarrow 368 Rings F). (ii) R is a Noetherian ring and every prime ideal of R is a maximal ideal. (iii) There exist a finite number of Noetherian rings $R_i (i = 1, \dots, n)$ whose \dagger maximal ideals are \dagger nilpotent such that R is the direct sum of the $R_i (i = 1, \dots, n)$. We say that the **restricted minimum condition** holds in a ring R if R/\mathfrak{a} is an Artinian ring for every nonzero ideal \mathfrak{a} of R ; the latter condition is satisfied if and only if R is either an Artinian ring or a Noetherian domain of \dagger Krull dimension 1. Every ideal of a Noetherian ring R can be expressed as the intersection of a finite number of \dagger primary ideals. Given a ring R and an R -module M , a submodule P of M is said to be a **primary submodule** of M if every element a of R that is a **zero divisor with respect to M/P** (i.e., there exists an $m \in M/P$ such that $m \neq 0$ and $am = 0$) is **nilpotent with respect to M/P** (i.e., there exists a natural number n such that $a^n(M/P) = 0$).

The property of ideals in Noetherian rings stated above can be generalized to the case of Noetherian modules: If an R -module M is a \dagger Noetherian module, then every submodule of M can be expressed as the intersection of a finite number of primary submodules.

Let R be a Noetherian ring, \mathfrak{a} an ideal of R , M a finite R -module, and N and N' submodules of M . Then we have (i) the **Artin-Rees lemma**: There exists a natural number r such that for all $n > r$, $\mathfrak{a}^n N \cap N' = \mathfrak{a}^{n-r} \cdot (\mathfrak{a}^r N \cap N')$. (ii) **Krull's intersection theorem**: $\bigcap_{n=1}^{\infty} \mathfrak{a}^n M = \{m \in M \mid \exists a \in \mathfrak{a} \text{ such that } (1-a)m = 0\}$ (hence, in particular, if \mathfrak{m} is the \dagger Jacobson radical of R , then $\bigcap_{n=1}^{\infty} \mathfrak{m}^n M = \{0\}$). (iii) **Krull's altitude theorem**: If \mathfrak{a} is generated by s elements and \mathfrak{p} is a \dagger minimal prime divisor of \mathfrak{a} , then the height of $\mathfrak{p} \leq s$.

B. Topology Defined by an Ideal

Let R be a ring, \mathfrak{a} an ideal of R , and M an R -module. Then the **\mathfrak{a} -adic topology** of M is defined to be the topology on M such that $\{\mathfrak{a}^n M \mid n = 1, 2, \dots\}$ is a \dagger base for the neighborhood system of zero. In particular, let R be Noetherian, M a finite R -module, and N a submodule of M . Then by the Artin-Rees lemma, the \mathfrak{a} -adic topology of N coincides with the topology on N as a subspace of M with the \mathfrak{a} -adic topology. Returning to the general case, M is a $\dagger T_0$ -space (under the \mathfrak{a} -adic topology) if and only if $\bigcap_{n=1}^{\infty} \mathfrak{a}^n M = \{0\}$.

or, in other words, if and only if M is a \dagger metric space, where the \dagger distance $d(a, b)$ between points a, b in M is defined to be $\inf\{2^{-n} \mid a - b \in \alpha^n M\}$. Moreover, if N is a submodule of M , then M/N is a T_0 -space if and only if N is a closed subset of M , that is, if and only if $\bigcap_{n=1}^{\infty} (N + \alpha^n M) = N$. A sequence $\{a_n\} = (a_1, a_2, \dots, a_n, \dots)$ is called a **Cauchy sequence** (under the α -adic topology) if $\forall n \exists N \forall r \forall s$ (with each of them a natural number) $a_{N+r} - a_{N+s} \in \alpha^n M$; for this it is sufficient that $\forall n \exists N \forall r \ a_{N+r+1} - a_{N+r} \in \alpha^n M$. If this sequence converges to zero (i.e., $\forall n \exists N \forall r \ a_{N+r} \in \alpha^n M$), it is called a **null sequence**. The set \mathfrak{M} of all Cauchy sequences in M becomes an R -module if we define their sum and multiplication by an element of R by $\{a_n\} + \{b_n\} = \{a_n + b_n\}$, $c\{a_n\} = \{ca_n\}$. Then the set \mathfrak{N} of all null sequences is a submodule of \mathfrak{M} . An element m of M is identified with the sequence (m, m, \dots, m, \dots) , and we regard M as a submodule of \mathfrak{M} . Then the R -module $\bar{M} = \mathfrak{M}/\mathfrak{N}$ is the \dagger completion of $M/(\bigcap_{n=1}^{\infty} \alpha^n M)$ (as a metric space under the α -adic topology). \bar{M} is called the **α -adic completion** of M . If α has a finite basis, then the topology of \bar{M} (as the completion) coincides with its α -adic topology. If $M = R$, we define a multiplication in \mathfrak{M} by $\{a_n\}\{b_n\} = \{a_n b_n\}$. In this case, \mathfrak{M} is a ring in which \mathfrak{N} is an ideal, and hence the completion $\bar{R} = \bar{M}$ is a ring. If $\alpha = \sum_{i=1}^r a_i R$, then considering the \dagger ring of formal power series $\tilde{R} = R[[x_1, \dots, x_r]]$ and its ideal $\tilde{n} = \bigcap_{n=1}^{\infty} (\sum_{i=1}^r (a_i - x_i) \tilde{R} + \alpha^n \tilde{R})$, we have $\bar{R} \cong \tilde{R}/\tilde{n}$.

C. Zariski Rings

For a Noetherian ring R and an ideal α of R , every element b of R such that $1 - b \in \alpha$ has an inverse in R if and only if every ideal of R is a closed subset of R under the α -adic topology. When this condition is satisfied, the ring R with the α -adic topology is called a **Zariski ring**; we often express this by saying that (R, α) is a Zariski ring. A Zariski ring is called **complete** if it is a complete topological space. The completion \bar{R} of the Zariski ring (R, α) has the $\alpha\bar{R}$ -adic topology, and $(\bar{R}, \alpha\bar{R})$ is a Zariski ring. Furthermore, (i) \bar{R} is a \dagger faithfully flat R -module; and (ii) when N is a submodule of a finite R -module M , then N is a closed subspace of M (under their α -adic topologies), and their completions are identified with $N \otimes_R \bar{R}$, $M \otimes_R \bar{R}$.

D. Local Rings

Suppose that R is a Noetherian ring having only a finite number of maximal ideals and J is

the Jacobson radical of R . Then the Zariski ring (R, J) is called a **semilocal ring**. Furthermore, if R has only one maximal ideal, then (R, J) is called a **local ring**. A ring that has only a finite number of maximal ideals is called a **quasisemilocal ring**; if it has only one maximal ideal, it is called a **quasilocal ring**. (In some literature, the terms *local ring* and *semilocal ring* are used under weaker conditions; in the weakest case, quasisemilocal rings and quasilocal rings are simply called semilocal rings and local rings, respectively, and local rings and semilocal rings in our sense are called **Noetherian local rings** and **Noetherian semilocal rings**, respectively.)

Assume that R is a semilocal ring with maximal ideals $\mathfrak{m}_1, \dots, \mathfrak{m}_n$ and the Jacobson radical $J = \mathfrak{m}_1 \cap \dots \cap \mathfrak{m}_n$. For every finite R -module M , we introduce the J -adic topology as its natural topology. The completion \bar{R} of R is a semilocal ring with maximal ideals $\mathfrak{m}_1 \bar{R}, \dots, \mathfrak{m}_n \bar{R}$ and is naturally isomorphic to the direct sum of the completions of the local rings $R_{\mathfrak{m}_i}$ ($i = 1, \dots, n$). Since R is a Zariski ring, (1) \bar{R} is faithfully flat; (2) submodules of M are closed subsets of M ; and (3) the completion of M is identified with $M \otimes_R \bar{R}$. If (R, \mathfrak{m}) is a **complete local ring** (i.e., a local ring and a complete Zariski ring at the same time), then R contains a subring I with the following properties: (i) I is a complete local ring, and $I/(\mathfrak{m} \cap I) = R/\mathfrak{m}$; and (ii) for the \dagger characteristic p of R/\mathfrak{m} (p is either zero or a prime number), $\mathfrak{m} \cap I = pI$. Therefore, if \mathfrak{m} is generated by n elements, then R is a homomorphic image of the ring of formal power series in n variables over I . This theorem is called the **structure theorem of complete local rings**, and I is called a **coefficient ring** of R . If R contains a field, then I is a field, called a **coefficient field** of R . A complete local ring is a \dagger Hensel ring.

When (R, \mathfrak{m}) is a local ring and $\sum_{i=1}^r x_i R$ is \mathfrak{m} -primary, then we have an inequality $r \geq (\dagger \text{Krull dimension of } R)$; if the equality holds, then we say that x_1, \dots, x_r form a **system of parameters** of R . Furthermore, if $\mathfrak{m} = \sum_{i=1}^r x_i R$, then we say that x_1, \dots, x_r form a **regular system of parameters** of R . A local ring that has a regular system of parameters is called a **regular local ring** (cf. \dagger Jacobian criterion). A regular local ring is a \dagger unique factorization domain. Let d be the Krull dimension of a local ring (R, \mathfrak{m}) . Then R is a regular local ring if and only if one of the following holds: (1) every R -module has finite \dagger homological dimension, (2) every R -module has homological dimension of at most d , or (3) the homological dimension of R/\mathfrak{m} (as an R -module) is finite (and actually coincides with d). A Noetherian ring R' is called a **regular ring** if R'_p is

a regular local ring for every prime ideal \mathfrak{p}' . A regular local ring is a regular ring.

Consider a local ring (R, \mathfrak{m}) and an \mathfrak{m} -primary ideal \mathfrak{q} . Then the length $l(n)$ of R/\mathfrak{q}^n (as an R -module) is a function of n . For a sufficiently large n , the length $l(n)$ can be expressed as a polynomial $f(n)$ in n with rational coefficients. The degree of $f(n)$ coincides with the Krull dimension d of R . The **multiplicity** of \mathfrak{q} is (coefficient of n^d in $f(n)$) $\times (d!)$. If x_1, \dots, x_d form a system of parameters, then (multiplicity of $\sum_{i=1}^d x_i R$) \leq (length of $R/\sum_{i=1}^d x_i R$); if the equality holds, then we call x_1, \dots, x_d a **distinct system of parameters**. A local ring that has a distinct system of parameters is called a **Macaulay local ring**. A local ring is a Macaulay local ring if and only if one of the following holds: (1) every system of parameters is a distinct system of parameters, or (2) if an ideal \mathfrak{a} of height s is generated by s elements, then every \mathfrak{p} -prime divisor of \mathfrak{a} is of height s . A regular local ring is a Macaulay local ring.

The notion of multiplicity can be also defined in general Noetherian rings [4]. Let R be a Noetherian ring. If $R_{\mathfrak{m}}$ is a Macaulay local ring for every maximal ideal \mathfrak{m} , then R is called a **locally Macaulay ring**. Furthermore, if height $\mathfrak{m} = \text{Krull dim } R$ for every maximal ideal \mathfrak{m} , then R is called a **Macaulay ring**. If R is a locally Macaulay ring, then the polynomial ring in a finite number of variables over R is also a locally Macaulay ring. In general, an ideal \mathfrak{a} is called an **unmixed ideal** (or **pure ideal**) if the height of every prime divisor of \mathfrak{a} coincides with height \mathfrak{a} ; otherwise, \mathfrak{a} is called a **mixed ideal**. Thus if R is a locally Macaulay ring, an ideal \mathfrak{a} of the polynomial ring $R[x_1, \dots, x_n]$ over R is generated by r elements, and height $\mathfrak{a} = r$, then \mathfrak{a} is unmixed (**unmixedness theorem**).

If the completion of a local ring R is a \mathfrak{p} -normal ring, then we say that R is **analytically normal**. If the completion of a semilocal ring R has no nilpotent element except zero, then we say that R is **analytically unramified**. A semilocal integral domain R which is a ring of quotients of a finitely generated ring over a field is analytically unramified. If R is a normal local ring, then R is analytically normal (O. Zariski).

Let (R, \mathfrak{m}) be a local ring, and let \mathfrak{q} be an \mathfrak{m} -primary ideal. Set $F_i = \mathfrak{q}^i / \mathfrak{q}^{i+1}$ ($i = 0, 1, 2, \dots$, $\mathfrak{q}^0 = R$). Let $a = a' \pmod{\mathfrak{q}^{i+1}} \in F_i$ and $b = b' \pmod{\mathfrak{q}^{j+1}} \in F_j$. We put $ab = a'b' \pmod{\mathfrak{q}^{i+j+1}} \in F_{i+j}$. Then the direct sum of modules $F = \sum_{i=0}^{\infty} F_i$ becomes a graded ring generated by F_1 over F_0 , in which F_i is the module of homogeneous elements of degree i . F , called the **form ring** (or **associated graded ring**) of R with respect to \mathfrak{q} , plays an important role in the

theory of local rings, particularly in the theory of multiplicity.

E. Chains of Prime Ideals

Let R be a Noetherian ring with prime ideals $\mathfrak{p}, \mathfrak{q}$ such that $\mathfrak{p} \subset \mathfrak{q}$. Consider the length n of a chain of prime ideals $\mathfrak{p} = \mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \dots \subsetneq \mathfrak{p}_n = \mathfrak{q}$ which cannot be refined any more. It is not true in general that n is uniquely determined by \mathfrak{p} and \mathfrak{q} (M. Nagata). However, n is uniquely determined for a rather large class of Noetherian rings, for instance the rings that are homomorphic images of locally Macaulay rings and, in particular, finitely generated rings over a \mathfrak{p} -Dedekind domain.

F. Integral Closures

Let R be a Noetherian integral domain with the field of quotients k , let K be a finite algebraic extension of k , and let \tilde{R} be the \mathfrak{p} -integral closure of R in K . Then (i) If R is of Krull dimension 1, then for an arbitrary ring R' such that $R \subset R' \subset K$ and for every nonzero ideal \mathfrak{a}' of R' , the quotient R'/\mathfrak{a}' is a finite $R/(\mathfrak{a}' \cap R)$ -module. In particular, R' is a Noetherian domain satisfying the restricted minimum condition. (ii) If R is of Krull dimension 2, then \tilde{R} is Noetherian. (iii) In general, \tilde{R} is a \mathfrak{p} -Krull ring, and for an arbitrary prime ideal \mathfrak{p} of R there are only a finite number of prime ideals $\tilde{\mathfrak{p}}$ of \tilde{R} such that $\mathfrak{p} = \tilde{\mathfrak{p}} \cap R$. For any of such $\tilde{\mathfrak{p}}$, the field of quotients of $\tilde{R}/\tilde{\mathfrak{p}}$ is a finite algebraic extension of that of R/\mathfrak{p} . Result (i) is called the **Krull-Akizuki theorem**. We say that R satisfies the **finiteness condition for integral extensions** if \tilde{R} is a finite R -module for any choice of K . A Noetherian ring R is called a **pseudogeometric ring**, or a **universally Japanese ring**, if R/\mathfrak{p} satisfies the finiteness condition for integral extensions for every prime ideal \mathfrak{p} . A ring is pseudogeometric if it is generated by a finite number of elements over a pseudogeometric ring.

G. History

J. W. R. Dedekind first introduced the concept of ideals in the theory of integers. The main objects studied in ring theory were subrings of number fields or function fields until M. Sono (*Mem. Coll. Sci. Univ. Kyoto*, 2 (1917), 3 (1918–1919)) originated an abstract study of Dedekind domains, which was followed by E. Noether (*Math. Ann.*, 83 (1921), 96 (1926)), who originated the theory of Noetherian rings.

W. Krull made further important contributions to the development of the theory of Noetherian rings and general commutative rings [1]. Many other authors, including E. Artin, Y. Akizuki, and S. Mori, also contributed to the theory. The theory of local rings was originated by Krull (*J. Reine Angew. Math.*, 179 (1938)) and developed by C. Chevalley (*Ann. Math.*, 44 (1943)), I. S. Cohen (*Trans. Amer. Math. Soc.*, 59 (1946)), and Zariski (*Ann. Inst. Fourier*, 2 (1950)), and later by many authors, including P. Samuel, Nagata, M. Auslander, D. A. Buchsbaum, and J.-P. Serre [4]. The theory of Noetherian rings is applied to algebraic geometry.

285 (VI.16) Non-Euclidean Geometry

A. History

The validity of the fifth postulate of Euclid's *Elements*, the \dagger axiom of parallels, has been a subject of argument ever since it was formulated (\rightarrow 139 Euclidean Geometry). At the beginning of the 18th century, G. Saccheri tried to prove the postulate by assuming the validity of other axioms. Under the hypothesis that the axiom does not hold, he deduced various extraordinary results. Although he

was mistaken in thinking that he had obtained a contradiction, his work is regarded as a forerunner to the study of **non-Euclidean geometry**.

At the beginning of the 19th century, N. I. Lobachevskii and J. Bolyai opened up the impasse by establishing a geometry based on postulates that contradict the fifth postulate. This geometry is called **hyperbolic geometry** or **Lobachevskii's non-Euclidean geometry**. Actually, a similar idea had been conceived by C. F. Gauss, but he refrained from publishing it because of likely misunderstanding by a public still strongly influenced by I. Kant's philosophy. On the other hand, B. Riemann constructed so-called **elliptic geometry** (or **Riemann's non-Euclidean geometry**), which is different from both Euclidean and hyperbolic geometry. Euclidean geometry (including the theory of similarity) is sometimes called **parabolic geometry**. In general, a space satisfying axioms that contradict Euclid's postulates is called a **non-Euclidean space**.

Around the turn of the 20th century, A. Cayley, F. Klein, and H. Poincaré constructed models of non-Euclidean spaces that are subsets of Euclidean spaces, and E. Beltrami constructed a differential geometric model. By means of these models, it was established that non-Euclidean geometries are consistent as long as there is no inconsistency in the underlying Euclidean geometries. On the other hand, D. Hilbert established a complete system of axioms for Euclidean geometry and showed, by constructing non-Euclidean models, that the axiom of parallels is independent of the other axioms (\rightarrow 155 Foundations of Geometry). The logical foundation of non-Euclidean geometries was thus clarified. Moreover, A. Einstein showed in his \dagger theory of relativity that actual space-time does not satisfy Euclidean axioms. Together with Euclidean spaces, non-Euclidean spaces are often used as fundamental models both in the problem of \dagger space forms and in the theory of \dagger symmetric spaces.

B. Axiomatic Considerations

Hilbert's system of axioms of plane Euclidean geometry consists of axioms of incidence, order, congruence, parallels, and continuity (\rightarrow 155 Foundations of Geometry). Specifically, the axiom of parallels is stated as follows: Suppose we are given a straight line and a point in a plane. If the straight line does not contain the point, then there exists only one line through the point that does not intersect the line.

The system of axioms of hyperbolic geometry is obtained by replacing the axiom of parallels by the following: Suppose we are given a straight line and a point in a plane. If the line does not contain the point, then there exist at least two lines that pass through the point without intersecting the line. (The other four groups of axioms are unaltered.) In this case, if l is a given line that does not contain a given point C , then there exist exactly two lines **parallel** to l that pass through C . We denote them by XY and $X'Y'$, and they are characterized as follows (Fig. 1): Any line that passes through C and lies in $\angle X'CY$ necessarily intersects l ; by contrast, neither the two lines XY , $X'Y'$ nor any line in $\angle XCY$ intersects l . Euclidean geometry can be considered as a "limit" of this geometry where the lines XY and $X'Y'$ coincide.

Fig. 1

In elliptic geometry, the axiom of parallels is replaced by the following: Suppose we are given a straight line and a point in a plane. If the line does not contain the point, then any line passing through the point intersects the line. In this case, the lines are closed curves, and the axioms of order must be modified. Specifically, in Euclidean geometry, the axioms of order are based on the notion of a point A lying between points B and C , where A, B, C are distinct points on a line. In elliptic geometry, however, to define order we utilize the notion of a pair A, C of points separating another pair B, D (and vice versa), where A, B, C, D are distinct points on a line. The axioms of order are modified accordingly.

The sum of inner angles of a triangle is smaller or greater than two right angles according as we use the axioms of hyperbolic or elliptic geometry.

C. The Projective-Geometric Point of View

We take \dagger projective coordinates in an n -dimensional, real \dagger projective space \mathbf{P}^n and consider a quadric hypersurface defined by $Q: ax_0^2 + x_1^2 + \dots + x_n^2 = 0, a \neq 0$ (\rightarrow 90 Coordinates; 343 Projective Geometry). We denote by G the group consisting of the totality of projective transformations of \mathbf{P}^n that leave Q

invariant. We call Q the **absolute** and call G the **group of congruent transformations**. When $a < 0$, then this Q is a real quadric hypersurface. In this case, there exists a domain H^n (the totality of points inside Q) whose boundary coincides with Q , and the group G acts \dagger transitively on H^n . The pair $\{G, H^n\}$ provides a model of hyperbolic geometry, and the n -dimensional **hyperbolic space** H^n is homeomorphic to an n -dimensional open cell. Points of H^n , points on Q , and points outside Q are called **ordinary points**, **points at infinity**, and **ultrafinite points** (or **ideal points**), respectively. Two lines on H^n are said to be parallel if they intersect on the absolute Q . Next, when $a > 0$, the absolute Q is an imaginary quadric hypersurface, and the group G acts transitively on \mathbf{P}^n . The pair $\{G, \mathbf{P}^n\}$ provides a model of elliptic geometry. The n -dimensional **elliptic space** \mathbf{P}^n is homeomorphic to n -dimensional real projective space; hence it is compact. In elliptic geometry, any two distinct lines in a plane necessarily intersect at a point. The above models $\{G, \mathbf{P}^n\}$ of non-Euclidean geometries are called **Klein's models**.

Let $\{G, H^n\}$ be a Klein's model, A, B distinct points in \mathbf{P}^n , l the line containing A, B , and I, J be two points where the line l meets Q (Fig. 2). If we denote by (A, B, I, J) the \dagger anharmonic ratio of these four points, then the **non-Euclidean distance** ρ between the points A and B is given by $\rho = a \log(A, B, I, J)$, a a constant. Next, let l, g be lines in H^n intersecting at a point D . In the plane determined by l and g , we draw two imaginary tangents u, v to the absolute through D . Denoting by (l, g, u, v) the anharmonic ratio of these four lines, the **non-Euclidean angle** θ between the lines l and g is given by $\theta = (1/2i) \log(l, g, u, v), i = \sqrt{-1}$. Generally, let O be a point in the projective space \mathbf{P}^n , and denote by p the \dagger polar of O with respect to the absolute. By counting the polar p doubly, it can be regarded as a quadric hypersurface, which will be denoted by S_0 . A quadric hypersurface S of H^n is called a **non-Euclidean hypersphere** if it belongs to the \dagger pencil of quadric hypersurfaces determined by Q and S_0 . S is called a **proper hypersphere**, a **limiting hypersphere**, or an **equidistant hypersurface** according as the center O is an ordi-

Fig. 2

nary point, a point at infinity, or an ultrainfinite point, respectively. In the case of elliptic geometry $\{G, \mathbf{P}^n\}$, the distance ρ between two points A and B is given by $\rho = (a/i) \cdot \log(A, B, I, J)$ as I, J are imaginary points. Moreover, we may get parabolic geometry as the "limit" ($a \rightarrow \infty$) of the geometry given by Klein's models.

D. The Conformal-Geometric Point of View

Let S^n be an n -dimensional † conformal space. If we take suitable $(n+2)$ -hyperspherical coordinates in S^n , the space S^n can be realized as a quadric hypersurface $x_1^2 + x_2^2 + \dots + x_n^2 - 2x_0x_\infty = 0$ in $(n+1)$ -dimensional real projective space \mathbf{P}^{n+1} . A point in \mathbf{P}^{n+1} represents a hypersphere in S^n (\rightarrow 76 Conformal Geometry; 90 Coordinates). We denote by \tilde{G} the group consisting of the totality of † Möbius transformations leaving invariant a (real, point, or imaginary) hypersphere Q . When Q is a real hypersphere, the space S^n is divided into Q and the two open cells H^n, H_∞^n . If we denote by G the totality of transformations of the group \tilde{G} that do not interchange H^n and H_∞^n , then G is a subgroup of index 2 of \tilde{G} . In this case, each of the pairs $\{G, H^n\}$ and $\{G, H_\infty^n\}$ provides a model of hyperbolic geometry. When Q is a point hypersphere, the space E^n obtained from S^n by omitting the point Q is homeomorphic to an open cell, and the pair $\{\tilde{G}, E^n\}$ provides a model of parabolic geometry. On the other hand, when Q is an imaginary hypersphere, \tilde{G} is isomorphic to the † orthogonal group $O(n+1)$. We call the pair $\{\tilde{G}, S^n\}$ a **spherical geometry** and S^n an n -dimensional **spherical space**. In this case two points x and x' are called equivalent if x' is the image of x by symmetry with respect to Q . The space P^n obtained from S^n by identifying equivalent points is homeomorphic to the n -dimensional real projective space. If we denote by G the group obtained from \tilde{G} by making its actions effective on P^n , then G is the factor group of \tilde{G} by a cyclic group $\mathbf{Z}_2 = \mathbf{Z}/2\mathbf{Z}$. The pair $\{G, P^n\}$ provides a model of elliptic geometry. These models are called **Poincaré's models**. They were introduced as a result of research on automorphic functions in the case $n=2$.

In Poincaré's model, every straight line is represented either by a circle orthogonal to Q or by a circle passing through Q according as Q is a (real or imaginary) hypersphere or a point hypersphere. In spherical geometry, however, straight lines are usually called great circles, and two distinct great circles lying on a 2-dimensional sphere necessarily intersect at two points that are symmetric with respect to Q . Also, in Poincaré's model the distance

between two points A and B is defined as before, by making use of the anharmonic ratio of four points A, B, I, J on a circle (Fig. 3) (\rightarrow 74 Complex Numbers G).

Fig. 3

E. The Differential-Geometric Point of View

An n -dimensional space M of † constant curvature is by definition a † Riemannian manifold whose line element ds is given by

$$ds^2 = \frac{dx_1^2 + dx_2^2 + \dots + dx_n^2}{\left(1 + \frac{K}{4}(x_1^2 + x_2^2 + \dots + x_n^2)\right)}$$

with respect to appropriate local coordinates, where K is a constant called the † sectional curvature (\rightarrow 364 Riemannian Manifolds). According as K is positive, zero, or negative, M can be considered locally as an elliptic space, Euclidean space, or hyperbolic space, respectively. In this case, lines are † geodesics of M , and the non-Euclidean distance and non-Euclidean angle are those defined in the Riemannian manifold. When $n=2$, a † simply connected and † complete space of positive constant curvature is † embedded in 3-dimensional Euclidean space as a sphere, and a space of negative constant curvature is † locally isometric to a **pseudosphere** (Fig. 4), which is a surface of revolution obtained by rotating a † tractrix around its asymptote. † Complete n -dimensional spaces of constant curvature ($n \geq 2$) are called **space forms**. A simply connected space form is necessarily one of spherical space, Euclidean space, or hyperbolic space. Each of these is a † universal covering manifold of a general connected space form with a curvature of the same sign, and the group of † covering transformations is isomor-

Fig. 4

phic to a †discontinuous subgroup of the group of congruent transformations.

Each of the spaces, Euclidean, non-Euclidean, and spherical, is a †homogeneous space on which the corresponding group of congruent transformations acts transitively. Actually, each of these spaces has the structure of a †symmetric Riemannian homogeneous space of rank 1.

286 (XII.21) Nonlinear Functional Analysis

A. General Remarks

At present, the theory of nonlinear problems is still not unified, and many individual results obtained for specific classes of problems are stated in the languages of the corresponding fields of study. However, there are some fundamental facts and methods of a general nature concerning nonlinear problems, which may be referred to as the subject matter of **nonlinear functional analysis**.

B. Iterative Methods

Let X be a †Banach space. Consider a nonlinear mapping $G: X \rightarrow X$ and the equation

$$Gx = 0 \quad (x \in X). \quad (1)$$

Set $F = I - G$. Then (1) can be written as

$$x = Fx. \quad (2)$$

F satisfies the **Lipschitz condition** if there exists a constant α such that

$$\|Fx - Fy\| \leq \alpha \|x - y\| \quad (3)$$

for all x, y in X . In particular, the mapping F is said to be **nonexpansive** if $0 < \alpha \leq 1$. If $0 < \alpha < 1$, then F is called a **contraction**. (Sometimes a nonexpansive mapping is also called a contraction.) A contraction F satisfies the **contraction principle**: F has a unique fixed point x_0 , and the **iteration**

$$x_{n+1} = Fx_n \quad (n = 1, 2, \dots)$$

with an arbitrary initial element x_1 always converges to x_0 [1–3]. Similar results hold for a contraction that is defined only on a †ball and leaves the ball invariant. This leads to †Newton's iterative process and the †implicit function theorem.

C. Methods of Monotonicity

By definition, a nonlinear mapping G from a †Hilbert space H to H is a **monotone** or **accretive operator** if

$$\operatorname{Re}(Gx - Gy, x - y) \geq 0 \quad (x, y \in H).$$

G. Minty [4] proved that if $G: H \rightarrow H$ is monotone and continuous, then $\lambda I + G$ is a mapping onto H for any $\lambda > 0$, and its inverse $(\lambda I + G)^{-1}$ is nonexpansive. He has also shown that in the hypothesis of the theorem, we can replace the continuity requirement for G by maximality of G within the class of accretive operators that are possibly multivalued. Various developments of Minty's ideas, including generalization of his results to Banach spaces and applications to partial differential equations, have been obtained by F. Browder (*Amer. Math. Soc. Proc. Symposia in Appl. Math.*, 17 (1965)), J. Leray and J. L. Lions (*Bull. Soc. Math. France*, 93 (1965)), J. L. Lions [5], W. Strauss, H. Brézis (*Amer. Math. Soc. Proc. Symposia in Pure Math.*, 18 (1970)), and others.

A mapping A is said to be **dissipative** if $-A$ is accretive. Dissipative mappings play a central role in the theory of nonexpansive semi-groups (\rightarrow Section X).

D. Topological Methods

In the geometric study of ordinary differential equations [6] some familiar theorems of topology and †differential topology have been strong tools, e.g., †Brouwer's fixed-point theorem is utilized to establish the existence of periodic solutions. However, in order to deal with nonlinear partial differential equations we have to generalize these theorems to infinite-dimensional cases. For example, a fixed-point theorem in an infinite-dimensional space was first obtained by G. D. Birkhoff and O. D.

Kellogg (*Trans. Amer. Math. Soc.*, 23 (1922), 95–115). The theory of the degree of mappings was generalized to the case of Banach spaces by J. Leray and J. Schauder [33] for the class of mappings of the form $I - F$, where F is a **compact** continuous mapping, i.e., the image by F of any bounded set is relatively compact. Let D be an open bounded set in a Banach space X and ∂D be its boundary. Let $F: \bar{D} \rightarrow X$ be a continuous compact mapping and Φ denote $I - F$. If a point p in X does not belong to $\Phi(\partial D)$, then we can define the **Leray-Schauder degree** $d(\Phi, p, D)$ of Φ relative to p [1–3]. The Leray-Schauder degree $d(\Phi, p, D)$ is an integer with the following properties: (i) $d(I, p, D) = 1$ if $p \in D$. If $p \notin \Phi(D)$, then $d(\Phi, p, D) = 0$. (ii) (Homotopy invariance) $d(\Phi, p, D)$ depends only on the compact homotopy class of $\Phi: \partial D \rightarrow X \setminus \{p\}$. More precisely, let $K: [0, 1] \times \partial D \rightarrow X$ be a continuous compact mapping such that $x + K(t, x) \neq p$ for any $t \in [0, 1]$ and any $x \in \partial D$. Let $\Phi_0(x) = x + K(0, x)$ and $\Phi_1(x) = x + K(1, x)$. Then $d(\Phi_0, p, D) = d(\Phi_1, p, D)$. (iii) If p and p' are in the same component of $X \setminus \Phi(\partial D)$, then $d(\Phi, p, D) = d(\Phi, p', D)$. (iv) (Continuity) $d(\Phi, p, D)$ is a continuous locally constant function of Φ (with respect to uniform convergence) and of $p \in X \setminus \Phi(\partial D)$. (v) (Domain decomposition) If D is the union of finite number of open disjoint sets D_j ($j = 1, 2, \dots, N$) with $\partial D_j \subset \partial D$ and $\Phi(x) \neq p$ on $\bigcup_{j=1}^N \partial D_j$, then $d(\Phi, p, D) = \sum_{j=1}^N d(\Phi, p, D_j)$. (vi) (Excision) If Δ is a closed subset of D on which $\Phi(x) \neq p$, then $d(\Phi, p, D) = d(\Phi, p, D \setminus \Delta)$. (vii) (Cartesian product formula) If $X = X_1 \oplus X_2$ with $D_i \subset X_i$, $\Phi = (\Phi_1, \Phi_2)$ with $\Phi_i: \bar{D}_i \rightarrow X_i$ ($i = 1, 2$), $D = D_1 \times D_2$, and $p = (p_1, p_2)$, then $d(\Phi, p, D) = d(\Phi_1, p_1, D_1) \times d(\Phi_2, p_2, D_2)$, provided that the right-hand side is well defined.

The degree of mapping of Φ is also defined for some proper Fredholm mapping Φ (\rightarrow Section E; K. D. Elworthy and A. J. Tromba [38]; [32]).

Brouwer's fixed-point theorem (\rightarrow 153 Fixed-Point Theorems) is generalized to **Schauder's fixed-point theorem**: A compact mapping F of a closed bounded convex set K in a Banach space X into itself has a fixed point. Using the Leray-Schauder degree theory, one has the **Leray-Schauder fixed-point theorem**: Let D be a bounded open set of a Banach space X containing the origin O . Let $F(x, t): \bar{D} \times [0, 1] \rightarrow X$ be a compact mapping such that $F(x, 0) \equiv 0$. Suppose that $F(x, t) \neq x$ for any $x \in \partial D$ and $t \in [0, 1]$. Then the compact mapping $F(x, 1)$ has a fixed point x in D [1–3].

Other homotopy invariants, such as * homotopy groups and * cohomotopy groups, are also used in nonlinear functional analysis [1, 3]. For instance we have the following

theorem of Shvarts (1964) [3]: Let X and Y be two Banach spaces. Let $D = \{x \in X \mid \|x\| < 1\}$ be the unit ball and $\partial D = \{x \in X \mid \|x\| = 1\}$ be the unit sphere of X . Suppose L is a fixed continuous linear * Fredholm operator from X to Y of index $p \geq 0$. Let PL be the set of compact perturbation of L mapping ∂D into $Y \setminus 0$, i.e., $PL = \{\Phi = L + K \mid K \text{ is a continuous compact mapping of } \partial D \text{ to } Y \text{ such that } \Phi(x) = Lx + K(x) \neq 0 \text{ for } x \in \partial D\}$. Two mappings Φ_0 and Φ_1 in PL are said to belong to the same **compact homotopy class** on ∂D if there exists a continuous compact mapping $h: [0, 1] \times \partial D \rightarrow Y$ such that $Lx + h(t, x) \neq 0$ for x in ∂D , $\Phi_0(x) = Lx + h(0, x)$, and $\Phi_1(x) = Lx + h(1, x)$.

Shvarts's theorem: Let L be a fixed continuous linear Fredholm mapping from X to Y of index $p \geq 0$. Then the compact homotopy classes on ∂D of PL are in one-to-one correspondence with the elements of the p th stable homotopy group $\pi_{n+p}(S^n)$ ($n \geq p + 1$) (\rightarrow 202 Homotopy Theory H).

Warning: The topological structure of an infinite-dimensional Hilbert or Banach space is quite different from that of a finite-dimensional Euclidean space. For instance, let X be a Hilbert space of infinite dimension, and let $D = \{x \in X \mid \|x\| < 1\}$ be its unit ball and $\partial D = \{x \in X \mid \|x\| = 1\}$ be the unit sphere of X . S. Kakutani (*Proc. Imp. Acad. Tokyo*, 19 (1943)) gave a fixed-point free continuous mapping of \bar{D} into itself if X is separable [1–3]. Thus naive generalization of the Brouwer fixed-point theorem is no longer true in infinite-dimensional spaces. V. Klee and C. Bessaga [17] proved that the unit sphere ∂D is C^∞ -diffeomorphic to X for an arbitrary Hilbert space X of infinite dimension. N. H. Kuiper proved that the group of invertible continuous linear operators on X is contractible if X is separable [3]. All this is in striking contrast to the well-known facts for finite-dimensional spaces (\rightarrow 202 Homotopy Theory, 427 Topology of Lie Groups and Homogeneous Spaces). This is the reason why compactness assumptions are made in the theorems mentioned above.

E. Calculus in Banach (or Locally Convex) Spaces

When one considers a nonlinear operator, it often happens that the domain and the range are neither linear spaces nor their open subsets. The domain might be a space of all smooth mappings of a compact manifold into another, and so might be the range. Such spaces have no linear structure, and hence linearity or semilinearity do not make sense in

general. The concept of infinite-dimensional manifolds is therefore introduced of necessity in nonlinear functional analysis.

Definition of differentiable mappings. Let E and F be real Banach spaces and let $L(E, F)$ ($= L(E)$ if $E = F$) be the Banach space of all bounded linear operators with uniform operator norm. Let U be an open subset of E and x a point of U . A mapping (= nonlinear operator) f of U into F is called **Gâteaux differentiable** at x if $\lim_{t \rightarrow 0} t^{-1}(f(x+ty) - f(x)) = df(x, y)$ exists for any $y \in E$. $df(x, y)$ is called the **Gâteaux derivative** of f at x . f is called **Fréchet differentiable** at x if there exists a linear operator $A \in L(E, F)$ such that $\lim_{y \rightarrow 0} \|f(x+y) - f(x) - Ay\|/\|y\| = 0$. A is called the **Fréchet derivative** of f at x and is denoted by $df(x)$ or $f'(x)$. f is Fréchet differentiable in U if and only if it is Gateaux differentiable, $df(x, y)$ is linear in y , and $\sup_{y \neq 0} \|df(x, y)\|/\|y\|$ is bounded [10].

Let U be an open subset of E . A mapping f of U into F is said to be of **class C^0** if it is continuous and to be of **class C^1** if it is Fréchet-differentiable at each point $x \in U$ and the differential $df(x) \in L(E, F)$ is continuous as a mapping of U into $L(E, F)$. The differential $df(x)$ is also called the **linearized operator**. If the mapping $df: U \rightarrow L(E, F)$ is of class C^{r-1} , then f is said to be of **class C^r** . $d(d^{r-1}f)(x)$ is written as $d^r f(x)$, and called the **r th differential** at x . $d^r f(x)$ is an r -linear, bounded, symmetric operator of $E \times \dots \times E$ (r times) into F . f is said to be of **class C^∞** if f is of class C^r for every r . For an open subset V of F , $f: U \rightarrow V$ is called a **C^r diffeomorphism** if f is a bijection and both f and f^{-1} are of class C^r .

A C^r mapping f of U into F is called a **Fredholm mapping (Fredholm map)** if $df(x) \in L(E, F)$ is a linear \dagger Fredholm operator for every $x \in U$. Since $\text{Ind } df(x)$ is constant if U is connected, that integer $\text{Ind } df(x)$ is called the **index** of f .

F. Taylor's Theorem and Its Converse

Let $f: U \rightarrow F$ be of class C^r ($r \geq 1$). A generalized Taylor theorem claims that f can be approximated by a polynomial mapping: Let $x \in U$ and $y \in E$ be sufficiently close to 0 so that $x + ty \in U$ for $0 \leq t \leq 1$. Then

$$f(x+y) = \sum_{k=0}^r \frac{1}{k!} d^k f(x)(y, \dots, y) + \int_0^1 \frac{(1-t)^{r-1}}{(r-1)!} \times \{d^r f(x+ty) - d^r f(x)\}(y, \dots, y) dt.$$

Let $L_{\text{sym}}^k(E, F)$ be the Banach space of all k -linear, bounded, symmetric operators of $E \times \dots \times E$ into F with the uniform topology. If for every k , $0 \leq k \leq r$, there exists a continuous

mapping $\varphi_k: U \rightarrow L_{\text{sym}}^k(E, F)$ such that

$$f(x+y) = \sum_{k=0}^r \frac{1}{k!} \varphi_k(x)(y, \dots, y) + o(\|y\|^r)$$

at every $x \in U$ and y sufficiently close to 0, then $f: U \rightarrow F$ is of class C^r , and $d^k f(x) = \varphi_k(x)$.

G. The Implicit Function Theorem

Using the notation above, let $f: U \rightarrow V$ be of class C^r , $r \geq 1$, and assume that $0 \in U$, $0 \in V$, and $f(0) = 0$, where 0 is the origin of E or F . Suppose there is an $A \in L(F, E)$, called the **right inverse** of $df(0)$, such that $df(0)A = 1_F$ (the identity). Then the following assertions hold: (i) The image of F under A , AF , is a closed subspace of E , and $E = \text{Ker } df(0) \oplus AF$. (ii) There are neighborhoods U_1, U_2, V' of the zeros of $\text{Ker } df(0)$, AF , F , respectively, such that $U_1 \oplus U_2 \subset U$ and such that the mapping $g: U_1 \oplus U_2 \rightarrow U_1 \oplus V'$ defined by $g(u, v) = (u, f(u, v))$ is a C^r -diffeomorphism. Therefore, denoting the inverse of g by $h = (h_1, h_2)$, we have $h_1(u, w) \equiv u$ and $f(u, h_2(u, w)) \equiv w$. The latter means that the nonlinear equation $f(u, v) = w$ can be solved with respect to v .

H. Existence and Uniqueness of Integral Curves

Using the notation above, let f be a C^r mapping ($r \geq 1$) of U into E . Since $U \times E$ is the \dagger tangent bundle of U , $(x, f(x))$ can be regarded as a C^r tangent vector field on U . The equation of \dagger integral curves is $(d/dt)x(t) = f(x(t))$. A local existence and uniqueness of solutions is stated as follows: For an arbitrarily fixed $x \in U$, there are $\varepsilon > 0$ and an open neighborhood W of x such that there exists uniquely a C^r mapping h of $W \times (-\varepsilon, \varepsilon)$ into U satisfying $(d/dt)h(w, t) = f(h(w, t))$ and $h(w, 0) \equiv w$.

Using this fact, one can prove the **Frobenius theorem**: Let E' be a closed linear subspace of E with a direct summand E'' , and let $f: U \rightarrow L(E', E'')$ be a C^r mapping ($r \geq 1$) such that $f(0) = 0$. To each $x \in U$ one associates a closed linear subspace $D_x = \{v, f(x)v\} | v \in E'\}$. The disjoint union $D = \bigcup_{x \in U} D_x$ can be regarded as a subbundle of the tangent bundle $U \times E$. A mapping \tilde{u} of U into E is called a **cross section** of D if $\tilde{u}(x) \in D_x$ for every $x \in U$. D is called **involutive** if for any two C^1 cross sections \tilde{u}, \tilde{v} of D , the Lie bracket product $[\tilde{u}, \tilde{v}]$ defined by $[\tilde{u}, \tilde{v}](x) = d\tilde{u}(x)(\tilde{v}(x)) - d\tilde{v}(x)(\tilde{u}(x))$ is again a cross section of D . Now suppose D is an involutive subbundle of $U \times E$. Then for an arbitrarily fixed $x \in U$, there are a neighborhood W

of x and a C^r diffeomorphism h of W onto a neighborhood of 0 of E such that $dh(x)(D_x) \equiv E'$. This fact shows that an involutive subbundle can be trivialized by a suitable change of local coordinate systems.

I. Local Theories on Locally Convex Spaces

All local theories mentioned in Sections E–H are constructed on Banach spaces. However, it is important in concrete applications to construct these theories on a wider class of locally convex topological linear spaces.

Let E, F be \dagger locally convex topological linear spaces, and let U be an open subset of E . A mapping $f: U \rightarrow F$ is said to be of class C^0 if it is continuous. f is said to be of class C^r if f is of class C^{r-1} and the following is fulfilled: For every $x \in U$, there is an r -linear continuous symmetric mapping $d^r f(x)$ of $E \times \dots \times E$ into F such that $d^r f: U \times E \times \dots \times E \rightarrow F$ is continuous. If we put

$$F(y) = f(x+y) - f(x) - df(x)(y) - \dots - \frac{1}{r!} d^r f(x)(y, \dots, y)$$

for every y sufficiently close to $0 \in E$, then the mapping G defined by

$$G(t, y) = \begin{cases} F(ty)/t^r, & t \neq 0, \\ 0, & t = 0, \end{cases} \quad (t \in \mathbf{R})$$

is continuous at $(0, 0) \in \mathbf{R} \times E$. The definitions of C^∞ mappings and C^r diffeomorphisms are given as in Section E.

J. Implicit Function Theorems in Locally Convex Spaces

The implicit function theorem does not hold in general locally convex spaces. However, since it is useful for nonlinear problems, several sufficient conditions are presently being studied. The following are some of them. We assume that $f: U \rightarrow F$ is a C^r mapping ($r \geq 1$) such that $f(0) = 0$ and that $df(0): E \rightarrow F$ has a continuous right inverse.

(i) If $\dim F < \infty$, the implicit function theorem holds just as in Section G.

(ii) An implicit function theorem that can be applied to nonlinear elliptic differential operators can be restated as follows. Suppose E, F are \dagger projective limit of families of Banach spaces $\{E^k, k \geq d\}$, $\{F^k, k \geq d\}$ and $U = E \cap U^d$, where U^d is an open subset of E^d . If $f: U \rightarrow F$ can be extended to a C^r mapping ($r \geq 2$) of $E^k \cap U^d$ into F^k for every $k \geq d$, if f satisfies the following inequalities, called a linear estimate

with respect to $|\cdot|_k$:

$$\begin{aligned} |df(x+y)(v)|_k &\leq C(|y|_k|v|_d + |y|_d|v|_k) \\ &\quad + P_k(|y|_{k-1})|v|_{k-1}, \quad k > d, \\ |d^2 f(x+y)(u, v)|_k &\leq C(|y|_k|u|_d|v|_d + |y|_d|u|_k|v|_d \\ &\quad + |y|_d|u|_d|v|_k) + P_k(|y|_{k-1})|u|_{k-1}|v|_{k-1}, \quad k > d, \end{aligned} \quad (4)$$

where $|\cdot|_k$ is the norm in E^k or F^k , C is a positive constant independent of k , and P_k is a polynomial with positive coefficients, and if a right inverse A of $df(0)$ satisfies the inequality of Gårding type,

$$|Au|_k \leq C'|u|_k + D_k|u|_{k-1}, \quad k > d, \quad (5)$$

where $C' > 0$ independent of k and $D_k > 0$, then the implicit function theorem holds just as in Section G, and the obtained mapping h satisfies the same inequalities as (4) [11].

(iii) Nash-Moser implicit function theorem.

Though linear estimates such as (4) hold for many differential operators, the second inequality (5) is sometimes out of order, especially if f is a nonlinear hyperbolic operator. However, one can often obtain instead of (5) a weaker inequality:

$$|Au|_k \leq C'|u|_{k+s} + D_k|u|_{k+s-1}, \quad s > 0.$$

J. Nash [37] and J. Moser [12] approximated such an operator A by some smoothing operators and proved an implicit function theorem under a certain additional condition. The Nash-Moser implicit function theorem was successfully applied to many difficult problems, e.g., the embedding problem of Riemannian manifolds [37], the small divisor problem of celestial mechanics [36], free boundary problems (e.g., L. Hörmander *Arch. Rational Mech. Anal.*, 62 (1976), 1–52), and other problems (e.g., S. Klainerman, *Comm. Pure Appl. Math.*, 33 (1980), 43–101; M. Kuranishi, *Amer. Math. Soc. Proc. Symposia in Pure Math.*, 30 (1977), 97–105).

(iv) Analytic implicit function theorem.

In cases (ii) and (iii), the spaces E, F were given as projective limits of Banach spaces. On the contrary, H. Jacobowitz considered the case where E, F are \dagger inductive limits of Banach spaces. For instance, the space E of the smooth functions can be approximated by a family of Banach spaces $\{E_\varepsilon | \varepsilon > 0\}$ of all real analytic functions with ε as the radius of convergence. Under this circumstance, certain conditions for f and the right inverse of $df(0)$ yield an implicit function theorem [13].

(v) Mather's implicit function theorem [14]. The difficulty of implicit function theorems in Fréchet spaces is concentrated in the following fact: Even if $df(0)$ has a right inverse and even if x is sufficiently close to 0, $df(x)$ may not have

a right inverse. If the implicit function theorem holds, such a phenomenon should not happen. In cases (ii)–(iv), several functional-analytic conditions exclude this pathological phenomenon. In some special cases, these conditions can be replaced by algebraic ones. J. Mather, using his division theorem, proved an implicit function theorem that was applied to the theory of singularities.

K. Infinite-Dimensional Manifolds

A Hausdorff space M is called a C^r **Banach manifold** modeled on a Banach space E if the following conditions are satisfied: (a) M is covered by a family of open subsets $\{U_\alpha\}_{\alpha \in A}$. For each U_α there are an open subset V_α of E and a homeomorphism ψ_α of U_α onto V_α . Such a pair is called a local coordinate system or a local chart of M . (b) If $U_\alpha \cap U_\beta \neq \emptyset$, $\psi_\alpha \psi_\beta^{-1}$ is a C^r -diffeomorphism of $\psi_\beta(U_\alpha \cap U_\beta)$ onto $\psi_\alpha(U_\alpha \cap U_\beta)$. (c) The index set A is maximal among those that satisfy (a) and (b).

If M (resp. M') is a C^r Banach manifold modeled on E (resp. E'), then so is $M \times M'$ modeled on $E \oplus E'$. A mapping $f: M \rightarrow M'$ is said to be of class C^r if f expressed through local coordinate systems is of class C^r .

Suppose M is covered by a family of local charts $\{(U_\alpha, \psi_\alpha)\}_{\alpha \in A}$. On the disjoint union $\bigcup_{\alpha \in A} U_\alpha \times E$, define an equivalence relation \sim as follows: For $(x, u) \in U_\alpha \times E$, $(y, v) \in U_\beta \times E$, $(x, u) \sim (y, v)$ if and only if $x = y$ and $d(\psi_\alpha \psi_\beta^{-1})(x)v = u$. The set of equivalence classes is called the **tangent bundle** of M , which will be denoted by T_M . There is another definition of the tangent bundle which uses the ring of C^r functions on M . However, since E is not reflexive in general, the latter gives us a different vector bundle. T_M is a C^{r-1} Banach manifold modeled on $E \oplus E$. The correspondence which sends $(x, u) \in \bigcup_{\alpha \in A} U_\alpha \times E$ to x induces a C^{r-1} mapping of T_M onto M , called the **projection** of T_M , denoted by π .

A topological group G is called a **Banach-Lie group** if G is a C^∞ Banach manifold and the group operation $(g, h) \rightarrow g^{-1}h$ is a C^∞ mapping of $G \times G$ into G . If E is a Banach space, then $GL(E)$, the group of all invertible bounded linear operators, is a Banach-Lie group under the uniform topology. If E is a Hilbert space, then the group of all unitary operators is also a Banach-Lie group under the same topology.

The concepts of manifolds and Lie groups are similarly defined when the model space is a Hilbert space or a Fréchet space. These are called a **Hilbert manifold** and a **Fréchet manifold**, respectively. For some differential

topologies on separable Hilbert manifolds \rightarrow
279 Morse Theory E.

L. Structures on Infinite-Dimensional Manifolds

Suppose M is a C^{r+1} Hilbert manifold modeled on E . At each $x \in M$, the tangent space $T_x M = \pi^{-1}(x)$ is a Hilbert space, linear-homeomorphic to E . M is called a C^r **Riemannian manifold** if there is defined an inner product $\langle u, v \rangle_x$ on each $T_x M$ such that $\langle \cdot, \cdot \rangle_x$ is of class C^r with respect to x . Existence of such a structure is ensured by using a partition of unity if M is paracompact.

Let M be a C^r Banach manifold ($r \geq 1$) modeled on a Banach space E . Each tangent space $T_x M$ is linear homeomorphic to E . M is called a C^r **Finsler manifold** if there is a norm $|u|_x$ defined on each $T_x M$ such that $| \cdot |_x$ is continuous with respect to x . A paracompact C^1 Banach manifold can have a C^1 Finsler structure.

Let M be a C^{r+2} Fréchet manifold ($r \geq 0$) and $C^{r+1}(M)$, $\Gamma^{r+1}(T_M)$ the spaces of all C^{r+1} functions and of all C^{r+1} vector fields on M , respectively. A bilinear mapping ∇ of $\Gamma^{r+1}(T_M) \times \Gamma^{r+1}(T_M)$ into $\Gamma^r(T_M)$ is called an **affine connection** on M if ∇ satisfies $\nabla_{f\tilde{u}}\tilde{v} = f\nabla_{\tilde{u}}\tilde{v}$, $\nabla_{\tilde{u}}f\tilde{v} = (\tilde{u}f)\tilde{v} + f\nabla_{\tilde{u}}\tilde{v}$ for every $\tilde{u}, \tilde{v} \in \Gamma^{r+1}(T_M)$, $f \in C^{r+1}(M)$. For an affine connection ∇ , $T(\tilde{u}, \tilde{v}) = \nabla_{\tilde{u}}\tilde{v} - \nabla_{\tilde{v}}\tilde{u} - [\tilde{u}, \tilde{v}]$ is called the **torsion tensor**, and $R(\tilde{u}, \tilde{v}) = \nabla_{\tilde{u}}\nabla_{\tilde{v}} - \nabla_{\tilde{v}}\nabla_{\tilde{u}} - \nabla_{[\tilde{u}, \tilde{v}]}$ is called the **curvature tensor** of ∇ . If M is a Riemannian manifold, then there exists a unique affine connection without torsion which leaves the Riemannian inner product parallel.

M. Local Linearization Theorems

Let M be a C^{r+1} Banach manifold ($r \geq 1$) modeled on E . Let \tilde{u} be a C^r vector field on M such that $\tilde{u}(x) \neq 0$ at $x \in M$. Then there are a neighborhood U_x of x and a C^r diffeomorphism ψ of U_x onto an open subset V of E such that $d\psi\tilde{u}(\psi^{-1}(y)) \equiv (y, v)$, $v \in E$, for every $y \in V$, where v does not depend on y .

N. Morse Lemma

Let M be a C^{r+2} Hilbert manifold and f be an \mathbf{R} -valued C^{r+2} function. Suppose x is a critical point of f , i.e., $df(x) = 0$. x is called a **nondegenerate critical point** if $d^2f(x)$ is a nondegenerate bilinear form. For such x there are a neighborhood U_x of x and a C^r diffeomorphism ψ of U_x onto an open neighborhood of 0 of the model space E such that $\psi(x) = 0$, and $f(\psi^{-1}(y)) = |Py|^2 - |(1-P)y|^2$, where P is an orthogonal

projection in E . $i_x = \dim(1 - P)E$ ($0 \leq i_x \leq \infty$) is called the **index** of the critical point x of f .

O. Submanifolds

A subset N of a C^r Banach manifold M modeled on E is called a C^r **submanifold** if at each point $x \in N$ there are a neighborhood U_x of x and a C^r -diffeomorphism ψ of U_x onto an open neighborhood V of 0 of E such that $\psi(x) = 0$ and $\psi(U_x \cap N) = V \cap F$, where F is a closed linear subspace of E . There are some other definitions of submanifolds. One of them requires in addition that F be a direct summand of E , and another uses instead of $U_x \cap N$ its connected component containing x . In the latter definition, a submanifold is not necessarily locally closed.

P. Sard-Smale Theorem

Although it is not easy to define nontrivial measures on infinite-dimensional manifolds, the concept "almost everywhere" can sometimes be replaced by that of residual sets. A subset of a topological space is called a \dagger residual set if it contains an intersection of countably many open dense subsets. A residual set in a complete metric space or in a \dagger Baire space is dense. S. Smale [15] extended \dagger Sard's theorem to infinite-dimensional manifolds as follows: Let M, N be C^r Banach manifolds and $f: M \rightarrow N$ be a C^r Fredholm mapping. If M is separable and $r > \max\{0, \text{Ind}(df(x))\}$ for each $x \in M$, then $R_f = N - f(C)$ is a residual subset of N , where C is the set of critical points of f , i.e., a point x where $df(x)$ is not surjective.

Q. Calculus of Variations and Infinite-Dimensional Manifolds

Many problems in the calculus of variations can be understood as problems seeking critical points of functions defined on infinite-dimensional manifolds. R. Palais and S. Smale set up the following Condition C and fixed a category of functions where the critical points can be chased through gradient-like vector fields [6].

Palais-Smale Condition C. Let f be a C^1 function on a C^1 Finsler manifold M . If S is any subset of M on which f is bounded but on which $|df(x)|$ is not bounded away from 0 , then there is a critical point of f adherent to S .

In general, it is not easy to examine Condition C for a concrete f . However, many concrete problems, where the Euler equations are nonlinear elliptic, satisfy Condition C.

Morse theory. Let M be a C^∞ complete Riemannian manifold and f a C^∞ function bounded below satisfying Condition C and having only nondegenerate critical points. Then, using the Morse lemma, one can make a \dagger handlebody decomposition of M by the same method as in the case of finite-dimensional manifolds (\rightarrow 279 Morse Theory).

Lyusternik-Shnirel'man theory. This theory, constructed on finite-dimensional manifolds, can be extended naturally to Finsler manifolds. Let M be a complete C^2 Finsler manifold and f a C^2 function satisfying Condition C and bounded below. Then f has at least $\text{cat}(M)$ critical points, where $\text{cat}(M) = m$ means that M can be covered by m closed contractible subsets of M but not by $m - 1$ ones. If there is no such integer, then we set $\text{cat}(M) = \infty$.

Both Morse theory and Lyusternik-Shnirel'man theory have been successfully employed in the global theory of the calculus of variations.

R. Bifurcation Theory

Bifurcation theory concerns itself with the structure of the zeros of the functional equation of w with a parameter λ :

$$G(\lambda, w) = 0. \quad (6)$$

In general, the state w satisfying (6) represents the equilibrium (time-independent or stationary) solution of the evolution equation

$$w_t = G(\lambda, w) \quad \text{and} \quad w(0) = w_0. \quad (7)$$

Here the evolution equation itself stems from a mathematical model describing natural phenomena, $w = w(t)$ stands for the state at time t , and λ is the set of parameters representing the physical environment. For example, in the \dagger Navier-Stokes equation appearing in fluid dynamics, $w(t)$ represents the unknown velocity field at time t and λ is the \dagger Reynolds number. It is important to study bifurcation phenomena because they typically accompany the transition to instability of the state when some characteristic parameter passes through a certain value, called a **critical value**.

Let X, Y , and Λ be real Banach spaces, and let $G(\lambda, w)$ be a mapping from $\Lambda \times X$ to Y . Suppose that there exists a mapping $\tilde{w}(\lambda): \Lambda \rightarrow X$ satisfying $G(\lambda, \tilde{w}(\lambda)) = 0$. One calls $(\lambda, \tilde{w}(\lambda))$ a trivial solution of (6).

$(\lambda_0, \tilde{w}(\lambda_0))$ is called a **bifurcation point** of $G(\lambda, w)$ (with respect to the trivial solution) if in any neighborhood of $(\lambda_0, \tilde{w}(\lambda_0))$ there exists a nontrivial solution of (6). (In general, there may appear another type of solution that is not connected with the trivial solution [20]).

Assume that $G(\lambda, w)$ is of class C^1 in some neighborhood of $(\lambda_0, \tilde{w}(\lambda_0))$ in $\Lambda \times X$. Then it follows from the implicit function theorem that $(\lambda_0, \tilde{w}(\lambda_0))$ is not a bifurcation point if $G_w(\lambda_0, \tilde{w}(\lambda_0))$, the Fréchet derivative of G with respect to w , is nonsingular.

S. The Principle of Linearized Stability

Closely tied to the phenomenon of bifurcation is the property of **stability**. Suppose that the dynamics of a physical system are governed by (7). Let $w(t; w_0)$ denote the solution of (7). An equilibrium solution $\tilde{w} = \tilde{w}(\lambda)$ is called **stable** if for any $\varepsilon > 0$ there exists a $\delta > 0$ such that $\|w(t; w_0) - \tilde{w}\| < \varepsilon$ for all $t > 0$ whenever $\|w_0 - \tilde{w}\| < \delta$. Furthermore, \tilde{w} is said to be **asymptotically stable** if, in addition, $w(t; w_0) \rightarrow \tilde{w}$ as $t \rightarrow \infty$.

By the **principle of linearized stability** we mean that the stability of an equilibrium solution \tilde{w} is determined formally by the spectrum of the linearized operator $G_w(\lambda, \tilde{w}(\lambda))$. Assume that $G_w(\lambda, \tilde{w}(\lambda))$ has only a point spectrum. Then (i) if $\tilde{w}(\lambda)$ is stable, the spectrum of $G_w(\lambda, \tilde{w}(\lambda))$ is contained in $\{z \in \mathbb{C} \mid \operatorname{Re} z \leq 0\}$, and (ii) if the spectrum of $G_w(\lambda, \tilde{w}(\lambda))$ is contained in $\{z \in \mathbb{C} \mid \operatorname{Re} z < 0\}$, \tilde{w} is asymptotically stable.

Suppose that as λ crosses a certain value λ_0 , one or more eigenvalues of $G_w(\lambda, \tilde{w}(\lambda))$ cross the imaginary axis from the left to the right half-plane, where $\tilde{w}(\lambda)$ is the known equilibrium solution. This is precisely the situation when $\tilde{w}(\lambda)$ becomes unstable. For notational simplicity, we put $u = w - \tilde{w}(\lambda)$ and $F(\lambda, u) = G(\lambda, u + \tilde{w}(\lambda))$.

T. Bifurcation from Simple Eigenvalues

Take $\Lambda = \mathbb{R}$. Let $F \in C^2(\mathbb{R} \times X, Y)$ be such that $F(\lambda, 0) = 0$ for any real λ . Set $L_0 = F_u(\lambda_0, 0)$, $L_1 = F_{\lambda u}(\lambda_0, 0)$, and suppose that (i) $\operatorname{Ker}(L_0)$ is spanned by $u_0 \neq 0$; (ii) $\operatorname{codim} R(L_0) = 1$; and (iii) $L_1 u_0 \notin R(L_0)$, where $R(L_0)$ denotes the range of L_0 . Then there exists a C^1 -curve $(\lambda, \psi): (-\delta, \delta) \rightarrow \mathbb{R} \times X$ defined on some interval $(-\delta, \delta)$ such that $\lambda(0) = \lambda_0$, $\psi(0) = 0$, and $F(\lambda(s), s(u_0 + \psi(s))) = 0$ for any $s \in (-\delta, \delta)$. Moreover, in a neighborhood of $(\lambda_0, 0)$ any zero of F either lies on this curve or is a trivial solution (M. G. Crandall and P. H. Rabinowitz, *J. Functional Anal.*, 8 (1971)).

In the above case, there exist only three possible situations of the curves (λ, φ) and $(\lambda, 0)$, called subcritical, supercritical, and transcritical bifurcations. In the third case, there occurs the so-called **exchange of stability** [19–21].

U. Bifurcation of Periodic Solutions (Hopf Bifurcation Theorem)

If $u(\lambda)$ loses stability by virtue of a pair of complex conjugate eigenvalues crossing the imaginary axis, then under suitable conditions one can prove the existence of bifurcating time-periodic solutions of (7). Rewrite equation (7) as

$$u_t + L_0 u + g(\lambda, u) = 0. \quad (8)$$

Suppose (i) $L_0: D(L_0) \subset X \rightarrow X$ is a densely defined linear operator on X such that $-L_0$ generates a strongly continuous semigroup on X , which is holomorphic on $X^{\mathbb{C}}$ (= the complexification of X). L_0 has compact resolvent; i is a simple eigenvalue of L_0 , and $ni \notin \sigma(L_0)$, the spectrum of L_0 , for $n = 0, 2, 3, \dots$. As a consequence of (i), if $r > -\operatorname{Re} \lambda$ for any $\lambda \in \sigma(L_0)$, then the fractional power $(rI + L_0)^\alpha$ for $\alpha \geq 0$ is well defined. Because their domains are independent of r , one can set $X_\alpha = D((rI + L_0)^\alpha)$, which are Banach spaces under the norm $\|u\|_\alpha = \|(rI + L_0)^\alpha u\|$. Suppose (ii) there exist an $\alpha \in [0, 1)$ and a neighborhood \mathcal{O} of $(0, 0)$ in $\mathbb{R} \times X$ such that $g \in C^2(\mathcal{O}, X_\alpha)$, where $C^k(\mathcal{O}, X_\alpha)$ denotes the space of all X_α -valued C^k functions defined on \mathcal{O} . Moreover $g(\lambda, 0) = 0$ if $(\lambda, 0) \in \mathcal{O}$, and $g_u(0, 0) = 0$. (iii) Let $\beta = \beta(\lambda)$ be a continuously differentiable function defined in a neighborhood of 0 such that $\beta(\lambda) \in \sigma(L_0 + g_u(\lambda, 0))$ and $\beta(0) = i$. Suppose that $\operatorname{Re} \beta'(0) \neq 0$. If assumptions (i), (ii) and (iii) are satisfied, then there exist a positive δ and continuously differentiable functions $(\rho, \lambda, u): (-\delta, \delta) \rightarrow \mathbb{R}^2 \times C^0(\mathbb{R}, X_\alpha)$ such that (a) for $0 < |s| < \delta$, $u(s)$ is a $2\pi\rho(s)$ -periodic solution of period $2\pi\rho(s)$ of (8) corresponding to $\lambda = \lambda(s)$; (b) $\rho(0) = 1$, $\lambda(0) = 0$, $u(0) = 0$, and $u(s) \neq 0$ if $s \neq 0$; and (c) any $2\pi\rho$ -periodic solution of (8) in $C_{2\pi\rho}^0(\mathbb{R}, X_\alpha)$ (= the space of $2\pi\rho$ -periodic continuous functions with value in X_α) with $|\rho - 1|$, $|\lambda|$ and $\|u\|$ sufficiently small is of the above form for some $|s| < \delta$ up to a translation of the real line. Moreover, if $g \in C^{k+1}(\mathcal{O}, X_\alpha)$, then the functions ρ, λ, u are of class C^k .

V. The Lyapunov-Schmidt Procedure

Suppose that $L(\lambda) = F_u(\lambda, 0)$ has at $\lambda = 0$ an n -fold eigenvalue at the origin, i.e., $\dim \operatorname{Ker} L(0) = n$, and assume that $X \subset Y$. Let $\operatorname{Ker} L(0)$ be spanned by $\varphi_1, \dots, \varphi_n$, and let P be the projection onto this linear subspace that commutes with $L(0)$. Then P must take the form $Pu = \sum_{j=1}^n \langle u, \varphi_j^* \rangle \varphi_j$, where the $\varphi_j^* \in Y^* \subset X^*$ are null functions of the adjoint operator $L(0)^*$ and $\langle \varphi_j, \varphi_k^* \rangle = \delta_{jk}$. P is a linear operator from Y to Y ; hence it can be regarded as a mapping from X to X as well, and $Q = I - P$ is a projec-

tion onto the range of $L(0)$ in Y . Using P and Q , the equation $F(\lambda, u) = 0$ can be decomposed into the system of equations

$$QF(\lambda, v + \psi) = 0 \quad \text{and} \quad PF(\lambda, v + \psi) = 0, \quad (9)$$

where $v = Pu$ and $\psi = Qu$. One solves the first equation for $\psi = \psi(\lambda, v)$ by the implicit function theorem, and then, substituting this into the second, one has the **bifurcation equation**

$$\tilde{F}(\lambda, v) = PF(\lambda, v + \psi(\lambda, v)) = 0. \quad (10)$$

Solutions of the bifurcation equation are in one-to-one correspondence with solutions of the original system sufficiently close to the bifurcation point.

There exists another method of reducing an infinite-dimensional problem to a finite-dimensional one, called the **center manifold theorem** [21, 39].

W. A Global Result

The following global result is due to P. H. Rabinowitz (*J. Functional Anal.*, 7 (1971)). Assume that $F(\lambda, u) = u - \lambda Lu + H(\lambda, u)$, where L is a compact linear operator and $H: \mathbf{R} \times X \rightarrow X$ is a compact mapping with $H(\lambda, u) = o(\|u\|)$ at 0 uniformly on bounded λ -intervals. Then, if μ^{-1} is an eigenvalue of L of odd multiplicity, $(\mu, 0)$ is a bifurcation point for F with respect to the trivial solution. Moreover, the closure of the set of nontrivial zeros of F contains a component that meets $(\mu, 0)$ and either is unbounded in $\mathbf{R} \times X$ or meets $(\hat{\mu}, 0)$, where $\mu \neq \hat{\mu}$ and $\hat{\mu}^{-1}$ is an eigenvalue of L .

The beginning of bifurcation theory seems to be in the celebrated work of H. Poincaré (*Acta Math.*, 7 (1885)).

X. Abstract Cauchy Problems

Suppose that we are given an **abstract Cauchy problem**

$$\frac{du}{dt} = Au \quad (t > 0), \quad (11)$$

$$u(+0) = a \quad (12)$$

in a Banach space X , where $a \in X$ and the nonlinear operator A is assumed, for simplicity, to be independent of t . If the domain $D(A)$ of A coincides with X and A is † Lipschitz continuous, we can reduce the abstract Cauchy problem to the † integral equation of Volterra type

$$u(t) = a + \int_0^t Au(s) ds,$$

and by applying the iteration procedure we can easily show that the abstract Cauchy problem has a uniquely determined solution.

A similar treatment works for a singular but mildly nonlinear A of the form $A = L + N$ if the linear operator L is the generator of a † strongly continuous semigroup e^{tL} in the sense of Hille-Yosida theory (\rightarrow 378 Semigroups of Operators and Evolution Equations) and the nonlinear mapping N is Lipschitz continuous. In this case, we reduce the problem to the integral equation

$$u(t) = e^{tL}a + \int_0^t e^{(t-s)L}Nu(s) ds.$$

Here, if we merely have to assure ourselves of the local existence of the solution, then N can merely be locally Lipschitz continuous; and in this case, N can even be singular to some extent if e^{tL} is † holomorphic in t [22, 23]. A typical application of this procedure was made by P. Sobolevskii, T. Kato, and H. Fujita to the Navier-Stokes equation (\rightarrow 204 Hydrodynamical Equations; 205 Hydrodynamics) to construct regular solutions [22].

† Galerkin's method (\rightarrow 304 Numerical Solution of Partial Differential Equations) is sometimes quite convenient for obtaining († weak) solutions of (11) and (12) [5]. Again, typical applications were made to the Navier-Stokes equations by E. Hopf and others [5, 24, 25]. To prove the convergence of approximate solutions constructed by Galerkin's method and subject to so-called energy estimates, we often make use of Aubin's compactness theorem concerning vector-valued functions [5].

Remarkable developments have taken place since 1964 for the case where A is dissipative, i.e., $-A$ is accretive. F. Browder [26] proved that if X is a Hilbert space and A is dissipative, then the mere continuity of A is sufficient for the † well-posedness of (11) and (12). Then Y. Kōmura [27] brought about a crucial advance by showing that if A is a (possibly multivalued and) maximal dissipative operator with $D(A)$ dense in the Hilbert space X , then (11) and (12) are uniquely solvable for any $a \in D(A)$. Furthermore, he founded the theory of **nonlinear semigroups of operators** by establishing a † nonlinear version of the Hille-Yosida theory for semigroups of † nonexpansive operators in Hilbert spaces [28]. Subsequent developments and applications were made in various directions by T. Kato (*J. Math. Soc. Japan*, 19 (1967)), M. Crandall and A. Pazy (*J. Functional Anal.*, 3 (1969)), H. Brézis and A. Pazy (*J. Functional Anal.*, 6 (1970)), S. Oharu (*J. Math. Soc. Japan*, 22 (1970)), M. Crandall and T. Liggett [29], Y. Konishi (*Proc. Japan Acad.*, 47 (1971)), and others. While Kōmura's original proof was based on the **Yosida approximation** $A(I - \varepsilon A)^{-1}$ ($\varepsilon \rightarrow 0$) for A , it is proved in [29] that in any Banach space a dissipative operator A that is maxi-

mal in a certain sense generates a nonlinear semigroup T_t by the **exponential formula**

$$T_t x = \lim_{n \rightarrow \infty} \left(I - \frac{t}{n} A \right)^{-n} x. \quad (13)$$

The scope of applications of the generating theorem (13) can be seen, e.g., in B. K. Quinn (*Comm. Pure Appl. Math.*, 24 (1971)), M. G. Crandall (*Israel J. Math.*, 12 (1972)), Y. Konishi (*Proc. Japan Acad.*, 48 (1972) and *J. Math. Soc. Japan*, 25 (1973)), and S. Aizawa (*Hiroshima Math. J.*, 6 (1976)).

Y. Nonlinear Semigroups in Banach Lattices

Let X be a Banach lattice (\rightarrow 310 Ordered Linear Spaces). An operator $A: X \supset D(A) \rightarrow X$ is said to be **dispersive** if for all $x, y \in D(A)$,

$$\|(x - y)^+\| \leq \|(x - y - \lambda(Ax - Ay))^+\| \quad (\forall \lambda > 0).$$

When a dispersive operator A satisfies the range condition $R(I - \lambda A) \supset D(A)$ for any $\lambda > 0$, it generates an **order-preserving semigroup** $T_t = e^{tA}$ on $\overline{D(A)}$: $\|(T_t x - T_t y)^+\| \leq \|(x - y)^+\|$ for $t > 0$. We have therefore the preservation of order: $x \leq y$ implies $T_t x \leq T_t y$. We can prove in particular that the order of initial data is inherited by the solutions of a nonlinear heat equation (Y. Konishi).

Remark. Various pathological phenomena arise when we do not restrict the form of A in the abstract Cauchy problem (11), (12). We cite merely the "blowing up" of solutions of Cauchy problems for *nonlinear heat equations (\rightarrow 291 Nonlinear Problems) and the nonlinear wave propagations described by nonlinear *Schrödinger equations (J. B. Bailon, T. Cazenave, and M. Figueira).

Z. Abstract Cauchy-Kovalevskaya Theorem in a Scale of Banach Spaces

T. Yamanaka (*Comment. Math. Univ. St. Paul*, 9 (1960)), L. V. Obsyannikov (*Soviet Math. Doklady*, 6 (1965) and 12 (1971)), F. Trèves (*Trans. Amer. Math. Soc.*, 150 (1970)), L. Nirenberg (*J. Differential Geometry*, 6 (1972)), and T. Nishida [30] discussed abstract treatments of classical Cauchy-Kovalevskaya theorem for partial differential equations: Let $S = \{B_\rho\}_{\rho > 0}$ be a collection of Banach spaces depending on the real parameter $\rho > 0$. Let $\|u\|_\rho$ denote the norm of an element $u \in B_\rho$. The collection S is called a **scale of Banach spaces** if, for any ρ and $\rho' < \rho$, $B_\rho \subset B_{\rho'}$ and $\|u\|_{\rho'} \leq \|u\|_\rho$ for any u in B_ρ . Consider in S the initial value problem of the form

$$\frac{du}{dt} = F(u(t), t), \quad |t| < \delta, \quad \text{and} \quad u(0) = 0. \quad (14)$$

286 Ref.

Nonlinear Functional Analysis

Assume the following conditions on F : (i) For some numbers $R > 0$, $\eta > 0$, $\rho_0 > 0$ and every pair of numbers ρ, ρ' such that $0 < \rho' < \rho < \rho_0$, $(u, t) \rightarrow F(u, t)$ is a continuous mapping of $\{u \in B_\rho \mid \|u\|_\rho < R\} \times \{t \mid |t| < \eta\}$ into $B_{\rho'}$. (ii) For any $\rho' < \rho < \rho_0$ and all $u, v \in B_\rho$ with $\|u\|_\rho < R$, $\|v\|_\rho < R$, and for any t , $|t| < \eta$, F satisfies $\|F(u, t) - F(v, t)\|_{\rho'} < C\|u - v\|_\rho / (\rho - \rho')$, where C is a constant independent of t, u, v, ρ , or ρ' . (iii) $F(0, t)$ is a continuous function of t , $|t| < \eta$, with values in B_ρ for every $\rho < \rho_0$ and satisfies, with a fixed constant K , $\|F(0, t)\|_\rho \leq K/(\rho_0 - \rho)$, $0 \leq \rho < \rho_0$.

Abstract Cauchy-Kovalevskaya theorem.

Under the preceding hypotheses there is a positive constant M such that there exists a unique function $u(t)$ which for every positive $\rho < \rho_0$ and $|t| < M(\rho_0 - \rho)$ is a continuously differentiable function of t with values in B_ρ , $\|u(t)\|_\rho < R$, and satisfies (14) (\rightarrow also [31]).

These results cover a theorem of M. Nagumo (*Japan. J. Math.*, 18 (1948)), which generalizes the classical Cauchy-Kovalevskaya theorem.

Nonlinear Lattice Dynamics

A. Lattice Dynamics

In order to elucidate certain characteristic features of nonlinear waves, **one-dimensional lattice** models have been studied. Around 1953, E. Fermi et al. performed computer experiments on nonlinear lattices to verify a generally accepted belief that nonlinear coupling between the normal modes of harmonic oscillators would lead to complete energy sharing between these modes. To their surprise, their nonlinear lattices yielded very little energy sharing at all; on the contrary, the interactions resulted in the recurrence of the initial state. These results were later interpreted in terms of solitons (\rightarrow 387 Solitons), i.e., nonlinear waves that preserve identity despite mutual interaction.

The equations of motion for a uniform 1-dimensional chain of particles of mass m with

nearest-neighbor interaction can be written as

$$m \frac{d^2 Q_n}{dt^2} = -\varphi'(Q_n - Q_{n-1}) + \varphi'(Q_{n+1} - Q_n) \\ (n = \dots, 1, 2, \dots).$$

It was shown that a lattice with a nonlinear interaction of the form

$$\varphi(r) = e^{-r} + r + \text{const.}$$

admits solutions in closed form. Later, it was shown that this lattice (the **exponential lattice** or the **Toda lattice**) is a completely **integrable system**.

It is convenient to introduce s_n , which is the generalized momentum canonically conjugate to the mutual displacement $r_n = Q_{n+1} - Q_n$. For a lattice with exponential interaction,

$$e^{-r_n} - 1 = ds_n/dt,$$

and if we introduce

$$S_n = \int^t s_n dt,$$

then the equations of motion can be written as

$$\log(1 + d^2 S_n / dt^2) = S_{n+1} + S_{n-1} - 2S_n,$$

and the displacements are given by

$$Q_n = S_n - S_{n+1}.$$

We have a solution

$$S_n = \log \{1 + e^{2(\alpha n + \beta t + \delta)}\},$$

where α and δ are arbitrary constants and $\beta = \pm \sinh \alpha$. The associated wave

$$e^{-r_n} - 1 = \beta^2 \text{sech}^2(\alpha n + \beta t + \delta)$$

represents a solitary wave or soliton.

The multisoliton (N -soliton) solution is given by

$$S_n = \log \det \Psi_n,$$

where Ψ_n is an $N \times N$ matrix whose elements are

$$(\Psi_n)_{jk} = \delta_{jk} + c_j c_k \frac{(Z_j Z_k)^{n+1}}{1 - Z_j Z_k} e^{(\beta_j + \beta_k)t}$$

with

$$Z_j = \pm e^{-\alpha_j},$$

$$\beta_j = \mp \sinh \alpha_j.$$

Asymptotically the wave reduces as $t \rightarrow \mp \infty$ to an assembly of solitons

$$e^{-r_n} - 1 = \sum_{j=1}^N \beta_j^2 \text{sech}^2(\alpha_j n + \beta_j t + \delta_j^\mp).$$

B. Conserved Quantities

The equations of motion for a periodic exponential lattice of N particles can be written

in a **Lax representation** $dL/dt = BL - LB$, where L and B are $N \times N$ matrices with the elements

$$L_{nn} = b_n, \quad L_{n,n+1} = L_{n+1,n} = a_n,$$

$$L_{1,N} = L_{N,1} = a_N,$$

$$B_{n,n+1} = -B_{n+1,n} = -a_n,$$

$$B_{1,N} = -B_{N,1} = a_N$$

(the other elements of L and B are all zero), with

$$a_n = \frac{1}{2} e^{-(Q_{n+1} - Q_n)/2},$$

$$b_n = \frac{1}{2} P_n \quad (P_n = dQ_n/dt).$$

The eigenvalues λ of L can be shown to be independent of time, and so the motion of the lattice is a spectrum-preserving deformation. Now, if we define $\{I_i\}$ by

$$\det(\lambda I - L) = \lambda^N + \lambda^{N-1} I_1 + \dots + \lambda I_{N-1} + I_N,$$

the $n\{I_i\}$ are polynomials of a_n and b_n . These are constants of motion that were discovered independently by M. Hénon and H. Flaschka. Thus the lattice has N conserved quantities; I_1 is related to the total momentum and I_2 to the total energy, but higher-index conserved quantities have no physical interpretation.

C. Method of Integration

Let L and B be the infinite matrices obtained from the foregoing ones in the limit $N \rightarrow \infty$. The eigenvalues λ of the equation

$$L\varphi = \lambda\varphi$$

are independent of time, and the time evolution of φ is given by the equation

$$d\varphi/dt = B\varphi.$$

If the motion in the lattice is restricted to a finite region, we can clearly speak of the scattering of the wave φ due to the deformation in the lattice. For a given initial motion $Q_n(0)$ and $P_n(0)$, or $L(0)$, we calculate the initial scattering data of asymptotic form $\varphi \sim z^n$ ($n \rightarrow \infty$). The **scattering data** consist of the reflection coefficient $R(z)$, the bound state eigenvalue $\lambda_j = -(z_j + z_j^{-1})/2$ ($\lambda_j < -1$ or $\lambda_j > 1$), and the coefficient c_j of the normalized bound state eigenfunction of asymptotic form $c_j z_j^n$ for $n \rightarrow \infty$.

From the initial data and the equations of motion for $n \rightarrow +\infty$, we get the scattering data at a later time t . In effect, we construct the kernel

$$F(m) = \frac{1}{2\pi i} \oint R(z, 0) e^{-(z - z^{-1})t} z^{m-1} dz \\ + \sum_j c_j^2(0) e^{-(z_j - z_j^{-1})t} z_j^m$$

of the discrete integral equation (**Gelfand-Levitan-Morchenko equation**)

$$\kappa(n, m) + F(n + m) + \sum_{n'=n+1}^{\infty} \kappa(n, n') F(n' + m) = 0, \\ m \geq n + 1.$$

After solving this equation for $\kappa(n, m)$, we calculate $K(n, n)$, given by

$$\frac{1}{[K(n, n)]^2} = 1 + F(2n) + \sum_{n'=n+1}^{\infty} \kappa(n, n') F(n' + n).$$

Then the initial value problem is solved in the form

$$e^{-(Q_n - Q_{n-1})} = \left[\frac{K(n, n)}{K(n-1, n-1)} \right]^2.$$

The solution can be given as $dQ_n/dt = s_n - s_{n+1}$, with

$$s_n = \kappa(n-1, n).$$

The simplest case $R(z) = 0$ yields the multi-soliton solution.

For the periodic case also, eigenvalues of the equations $L\varphi = \mu\varphi$ and $d\varphi/dt = B\varphi$, under suitable boundary conditions and for certain initial data, give sufficient information to construct a solution to the initial value problem. Such a method of obtaining a general solution for the periodic lattice was developed by E. Date and S. Tanaka, and independently by M. Kac and P. Van Moerbeke. Following Date and Tanaka, the solution can be written in terms of the multivariable theta function, or the Riemann theta function \mathfrak{J} , as

$$P_n = \frac{d}{dt} \log \frac{\mathfrak{J}(\alpha n + \beta t + \delta)}{\mathfrak{J}(\alpha(n+1) + \beta t + \delta)} + \text{const.},$$

where α , β , and δ are certain vector constants.

There has been much activity recently toward interpreting the integrability of the Toda lattice in terms of Lie algebras (B. Kostant [9]).

288 (XIII.10) Nonlinear Ordinary Differential Equations (Global Theory)

A. General Remarks

Many well-known functions (with the notable exception of the Γ -function), such as the exponential, trigonometric, elliptic, and automorphic functions, satisfy ordinary differential equations of simple forms. For the purpose of finding new transcendental functions, P. Painlevé initiated the systematic study of the equation

$$F(x, y, y', \dots, y^{(n)}) = 0 \quad (1)$$

in the complex domain. To investigate the solution in its whole domain of definition, he assumed that F is a polynomial in $y, y', \dots, y^{(n)}$ whose coefficients are analytic in x . Such an equation is called an **algebraic differential equation**. If F is linear in $y^{(n)}$, then (1) is written as

$$y^{(n)} = \frac{P(x, y, y', \dots, y^{(n-1)})}{Q(x, y, y', \dots, y^{(n-1)})}, \quad (2)$$

where P and Q are polynomials in $y, y', \dots, y^{(n-1)}$ with coefficients that are analytic functions of x . Equation (2) is called a **rational differential equation**.

If F is linear in $y, y', \dots, y^{(n)}$, i.e., (1) is a linear differential equation, and if the coefficient of $y^{(n)}$ is 1, then singular points of solutions are situated at the singular points of the coefficients (\rightarrow 254 Linear Ordinary Differential Equations (Local Theory)). If F is not linear, then singular points of solutions of (1) are divided into two categories, one consisting of those points whose positions are determined by the equation itself and are independent of individual solutions, and the other consisting of those points whose positions depend on the

choice of particular solutions. In other words, the singularities of the first category appear independently of the choice of arbitrary constants involved in the general solution, while those of the second category depend on the choice of the arbitrary constants. The former are called **fixed singularities** and the latter **movable singularities**. The linear differential equation (1) has fixed singularities only, which are situated at the singularities of the coefficients. In the same way, [†]branch points of solutions can be classified into two kinds, **fixed branch points** and **movable branch points**.

B. Algebraic Differential Equations of the First Order

Consider the equation

$$y' = \frac{P(x, y)}{Q(x, y)}, \quad (3)$$

where P and Q are relatively prime polynomials in x, y . The fixed singular points of (3) are defined to be points ξ, ξ' with the following properties: (i) $Q(\xi, y) \equiv 0$. (ii) $Q(\xi', y) \not\equiv 0$, $P(\xi', y) = Q(\xi', y) = 0$ have a root $y = \eta'$. (iii) If, in (ii), we substitute $1/z$ for y and if the same relation (ii) holds for $x = \xi$ and $z = 0$, we count such a value ξ_1 as a fixed singular point. (iv) We transform equation (3) by setting $x = 1/t$. If the value $t = 0$ satisfies (i) or (ii) for this transformed equation, we count ∞ as a singular point ξ or ξ' accordingly. The points ξ, ξ' are, in general, [†]transcendental singularities of solutions, and the points ξ' cannot be [†]essential singularities of solutions but may be [†]ordinary transcendental singularities. A singular point of a solution different from ξ and ξ' is an [†]algebraic singular point, and for any point distinct from ξ and ξ' , equation (3) admits a solution with an algebraic singularity at this point. A necessary and sufficient condition that (3) has no movable branch point is that (3) be a [†]Riccati equation.

Consider the algebraic differential equation of the first order

$$F(x, y, y') = 0. \quad (4)$$

After defining the fixed singular points ξ and ξ' of (4), where the algebraic function of x, y defined by (4) has bad singularities, Painlevé proved that movable singularities of solutions are algebraic. Before Painlevé's work, L. Fuchs gave a necessary and sufficient condition that (4) has no movable branch points, and then H. Poincaré showed that if this condition is satisfied, then (4) is either reducible to the Riccati equation if $g = 0$, integrable by the use of elliptic functions if $g = 1$, or algebraically integrable if $g > 1$, where, with x the independent vari-

able, g denotes the [†]genus of the algebraic curve defined by (4). Painlevé found that there were gaps in the proofs of Fuchs and Poincaré and completed these by proving his theorem and the following one: Let $\varphi(x, y_0, x_0)$ be the solution of (4) satisfying the initial condition $y(x_0) = y_0$. Let \bar{x}, \bar{x}_0 be points different from ξ and ξ' , and let L be a curve connecting \bar{x}_0 to \bar{x} and not passing through any ξ or ξ' . If we denote by $\varphi_L(\bar{x}, y_0, \bar{x}_0)$ the value at $x = \bar{x}$ of the branch obtained by continuing $\varphi(x, y_0, \bar{x}_0)$ analytically in a neighborhood of L and regard $\varphi_L(\bar{x}, y_0, \bar{x}_0)$ as a function of y_0 , then $\varphi_L(\bar{x}, y_0, \bar{x}_0)$ coincides, in a neighborhood of every point $y_0 = b$, with several branches of an [†]algebraic function of y_0 . Painlevé studied the case when the general solution is finitely many-valued and gave a condition for $\varphi(x, y_0, x_0)$ to be an algebraic function of y_0 .

When equation (4) does not contain x explicitly, no movable branch points appear if and only if all solutions are single-valued, and then the solutions are expressible in terms of rational, exponential, and elliptic functions. Such an equation is called a **Briot-Bouquet differential equation**.

J. Malmquist proved, by using P. Boutroux's method of studying the behavior of solutions in the neighborhood of a fixed singularity, that if equation (4) admits at least one solution that has an essential singularity and is finitely many-valued and free from movable branch points around this singularity, then (4) is an equation without movable branch points. If (4) admits a solution that is a finitely many-valued transcendental function, then an algebraic transformation may be applied to (4) so that it will become an equation without movable branch points. It is an immediate consequence of the first assertion that if (3) admits a solution that has an essential singularity and is finitely many-valued and free from movable branch points around the singularity, then (3) is a Riccati equation.

Later, equations (3) and (4) were studied by M. Hukuhara, K. Yosida, T. Satō, T. Kimura, and T. Matuda. The following results are due to Kimura. If a solution $\varphi(x)$ of (3) has an essential singularity at $x = \xi$, then, in an arbitrary neighborhood of ξ , $\varphi(x)$ assumes every value with the exception of the roots of $P(\xi, y) = 0$. If (3) is not a Riccati equation, it is determined by a finite number of algebraic processes whether or not (3) admits a solution that has an essential singularity at $x = \xi$ and has no movable branch point around ξ . If (3) admits such a solution, then the singularity is a [†]logarithmic branch point. For an essential singularity of a solution there exists, in general, a direction similar to a [†]Julia's direction, which was investigated by Hukuhara and

Kimura. Matuda studied in detail the behavior of solutions as x tends to ξ along a half-line and concluded that, except for some special cases, any solution tends to a certain value as x tends to ξ along a half-line. To obtain algebraic solutions C. Briot and J. C. Bouquet devised a method similar to [†]Puiseux expansion in the theory of algebraic functions. Hukuhara improved their method and succeeded in reducing (3) to several differential equations of standard forms in a neighborhood of $x = \xi$. This enables us to apply the local theory to the global study. Hukuhara's method was used by Kimura and Matuda to obtain the results discussed in this paragraph.

C. Algebraic Differential Equations of the Second Order

For second-order algebraic differential equations we can pose the same problems as for first-order equations: When do these equations have single-valued or finitely many-valued general solutions? What new transcendental functions are needed to integrate such equations? These problems, studied by E. Picard and Painlevé, are difficult because of the existence of movable transcendental singularities. However, Painlevé succeeded in determining rational differential equations of the second order without movable branch points. Such equations, with the exception of those that are integrated by the use of solutions of the first-order and linear differential equations, can be transformed by rational transformations into one of the following six differential equations:

$$(I) \quad y'' = 6y^2 + x,$$

$$(II) \quad y'' = 2y^3 + xy + \alpha,$$

$$(III) \quad y'' = \frac{y'^2}{y} - \frac{y'}{x} + \frac{\alpha y^2 + \beta}{x} + \gamma y^3 + \frac{\delta}{y},$$

$$(IV) \quad y'' = \frac{y'^2}{2y} + \frac{3y^3}{2} + 4xy^2 + 2(x^2 - \alpha)y + \frac{\beta}{y},$$

$$(V) \quad y'' = y'^2 \left(\frac{1}{2y} + \frac{1}{y-1} \right) - \frac{y'}{x} + \frac{(y-1)^2}{x^2} \left(\alpha y + \frac{\beta}{y} \right) + \frac{\gamma y}{x} + \frac{\delta y(y+1)}{y-1},$$

$$(VI) \quad y'' = \frac{y'^2}{2} \left(\frac{1}{y} + \frac{1}{y-1} + \frac{1}{y-x} \right) - y' \left(\frac{1}{x} + \frac{1}{x-1} + \frac{1}{y-x} \right) + \frac{y(y-1)(y-x)}{x^2(x-1)^2} \\ \times \left\{ \alpha + \frac{\beta x}{y^2} + \frac{\gamma(x-1)}{(y-1)^2} + \frac{\delta x(x-1)}{(y-x)^2} \right\},$$

where α , β , γ , and δ are constants. These equa-

tions and their solutions are called **Painlevé equations** and **Painlevé transcendental functions**, respectively. Equation (VI) was discovered by B. Gambier, who found an omission in Painlevé's calculations. All solutions of (I) are single-valued, and their properties were investigated by Boutroux. The solutions of (VI) have, in general, logarithmic branch points at $x=0, 1, \infty$ and were studied by R. Garnier.

The case when the equation is of degree 2 with respect to y'' was studied by Malmquist and F. Tricomi.

The following facts are known concerning movable transcendental singularities of the rational equation $y'' = P(x, y, y')/Q(x, y, y')$, where P and Q are relatively prime polynomials (Kimura). Let p, q be the degrees of P and Q with respect to y' . If $p > q + 2$, then any solution $\varphi(x)$ admits no movable essential singularities, but its derivative $\varphi'(x)$ may admit such singularities. If $p > q + 2$ and Q is not decomposable as $Q_1(x, y)Q_2(x, y, y')$, then neither φ nor φ' admits movable essential singularities. If $p \leq q + 2$, then both φ and φ' may have movable essential singularities. If $p \leq q + 2$ and Q is not decomposable as above, then φ' has no movable essential singularities. If, for a solution $\varphi(x)$, $x=a$ is a movable essential singularity of $\varphi(x)$ or $\varphi'(x)$, the $\varphi(x)$ or $\varphi'(x)$ assumes all values other than a finite number of exceptional values in an arbitrary neighborhood of $x=a$. If $p > q + 2$, then every solution possesses [†]Iversen's property, and hence the set of movable singularities is not a continuum.

D. Higher-Order Equations and Other Equations

Painlevé's method of obtaining the second-order equations without movable branch points is applicable to higher-order equations. The determination of third-order equations without movable branch points was attempted by Painlevé, J. Chazy, and Garnier by the use of this method, but is not yet complete. Chazy studied in detail an equation of the form

$$y''' = \frac{(1-1/n)y''^2}{y'} + b(y)y'y'' + c(y)y'^3$$

and showed that when $n = -2$ and $b(y) = 0$, [†]Fuchsian and [†]Kleinian functions are obtained as solutions (\rightarrow 32 Automorphic Functions).

R. Fuchs, a son of L. Fuchs, derived equation (VI), at almost the same time as Gambier, from the study of [†]monodromy groups. He showed that the monodromy group of the

equation

$$\frac{1}{z} \frac{d^2 z}{dt^2} = \left(\frac{\alpha}{t^2} + \frac{\beta}{(t-1)^2} + \frac{\gamma}{(t-x)^2} + \frac{\delta}{t(t-1)} + \frac{3}{4(t-y)^2} + \frac{a}{t(t-1)(t-x)} + \frac{b}{t(t-1)(t-y)} \right)$$

remains invariant as the singularity x varies if and only if α , β , γ , and δ remain constant; the singularity y , considered as a function of x , satisfies equation (VI); and a and b are rational functions of x and y and y' . Investigating a second-order linear differential equation of Fuchsian type with \dagger regular singularities $0, 1, \infty, x_1, \dots, x_n, y_1, \dots, y_n$ where y_1, \dots, y_n are apparent fixed singularities, Garnier was led, under the hypothesis that the monodromy group of this equation remains invariant as x_1, \dots, x_n vary, to a \dagger completely integrable system of partial differential equations and showed that a symmetric function of y_1, \dots, y_n , considered as a function of any one of x_1, \dots, x_n , satisfies an equation without movable branch points (\rightarrow 253 Linear Ordinary Differential Equations (Global Theory)).

For nonalgebraic equations, movable branch points appear even in the first-order case. Kimura obtained a sufficient condition that for an equation $F(x, y, y') = 0$, where F is a polynomial of y' with meromorphic coefficients in x, y , every solution has Iversen's property in a domain of the complex plane.

It was shown by O. Hölder that the Γ -function satisfies no algebraic differential equation. Also, if a function meromorphic in the unit circle is of \dagger order ∞ , then it satisfies no algebraic differential equation.

289 (XIII.9) Nonlinear Ordinary Differential Equations (Local Theory)

A. General Remarks

Consider a system of n differential equations

$$dy_j/dx = f_j(x, y_1, \dots, y_n), \quad j = 1, \dots, n, \quad (1)$$

where the f_j are analytic functions of x, y_1, \dots, y_n . To simplify the notation, we use vector notation \mathbf{y} instead of (y_1, \dots, y_n) . If all the f_j are holomorphic at a point $(x, \mathbf{y}) = (a, \mathbf{b})$, there exists one and only one solution $\mathbf{y}(x)$ for (1) such that $\mathbf{y} \rightarrow \mathbf{b}$ as $x \rightarrow a$ and $\mathbf{y}(x)$ is holomorphic at $x = a$. We say that a point (a, \mathbf{b}) is a **singular point** of the system (1) if it is a singular point of f_j for some j . The well-known \dagger Cauchy's existence theorem can no longer be applied to the case when (a, \mathbf{b}) is a singular point of system (1). In this case, the following three problems arise naturally: (i) to determine whether solutions $\mathbf{y}(x)$ such that $\mathbf{y}(x) \rightarrow \mathbf{b}$ as $x \rightarrow a$ exist, and if they exist, to determine the number of independent solutions; (ii) to construct analytic expressions for solutions $\mathbf{y}(x)$ such that $\mathbf{y}(x) \rightarrow \mathbf{b}$ as $x \rightarrow a$ or, in a slightly more general way, analytic expressions for bounded solutions $\mathbf{y}(x)$ such that the values of $(x, \mathbf{y}(x))$ stay in a neighborhood of the singular point (a, \mathbf{b}) ; (iii) to investigate the properties of these solutions. These three problems are called **local problems**, since only those solutions in a neighborhood of the singular point (a, \mathbf{b}) are considered. However, even when $n = 1$, the study of local problems is very difficult except for the case of singular points of particular types at which the functions f_j are meromorphic.

When $n > 1$, the problem becomes even harder; research on this case lags that for $n = 1$. In the subsequent discussion we assume without loss of generality that $a = 0, \mathbf{b} = \mathbf{0}$.

B. The Case of a Single Equation

Consider the equation

$$dy/dx = Y(x, y)/X(x, y), \quad (2)$$

where X and Y are holomorphic functions of (x, y) at $(0, 0)$, $x, y \in \mathbb{C}$. When $X(0, 0) = 0$ and

Nonlinear ODEs (Local Theory)

$Y(0,0) \neq 0$, we can rewrite equation (2) in the form $dx/dy = X(x,y)/Y(x,y)$, and we see that (i) if $X(0,y) \neq 0$, equation (2) has one and only one solution $y(x)$ which is algebraic at $x=0$ and tends to 0 as $x \rightarrow 0$; (ii) if $X(0,y) \equiv 0$, there is no solution of equation (2) such that $y \rightarrow 0$ as $x \rightarrow 0$.

The case where $X(0,0)=0$ and $Y(0,0)=0$ was first studied by C. A. A. Briot and J. C. Bouquet. In order to obtain algebraic solutions they introduced a method similar to [†]Puiseux expansion in the theory of algebraic functions. A. R. Forsyth and J. Malmquist studied a problem of reduction for equation (2) by using the Briot-Bouquet method. The theory of reduction was completed by M. Hukuhara, who divided a neighborhood of $(0,0)$ into a finite number of subdomains in such a way that (i) the union of these subdomains covers the given neighborhood of $(0,0)$ completely; (ii) in each of these subdomains equation (2) takes one of eight canonical forms. Hukuhara investigated the properties of the solutions for these canonical forms. Among them, the following two are well known as the **Briot-Bouquet differential equations**:

$$x dy/dx = f(x, y), \quad f(0,0)=0, \quad (3)$$

$$x^{\sigma+1} dy/dx = f(x, y),$$

$$f(0,0)=0, \quad \sigma \geq 1 \text{ is an integer.} \quad (4)$$

C. Systems of Differential Equations

When y is a vector with components (y_j) , equations (3) and (4) can be written as

$$x dy_j/dx = f_j(x, y_1, \dots, y_n), \quad j=1, \dots, n, \quad (5)$$

$$x^{\sigma+1} dy_j/dx = f_j(x, y_1, \dots, y_n), \quad j=1, \dots, n. \quad (6)$$

After Briot and Bouquet, the singular points of these types were studied by many authors, including Poincaré, E. Picard, H. Dulac, Malmquist, W. J. Trjitzinski, and Hukuhara. A method of constructing solutions of these equations consists of two parts: (i) formally transforming the given equations into simplified or reduced equations of the simplest possible form by applying a formal transformation of the type

$$y = \sum p_{kl} x^k z^l \quad (7)$$

or

$$y_j = \sum p_{k_0 k_1 \dots k_n} x^{k_0} z_1^{k_1} \dots z_n^{k_n}, \quad j=1, 2, \dots, n; \quad (8)$$

(ii) verifying convergence or the validity of [†]asymptotic expansions for the **formal solutions** of the given equations, which are obtained by substituting bounded solutions of the equations satisfied by z or z_j into (7) or (8).

By studying these analytic expressions, the properties of the solutions can be clarified.

D. Properties of Solutions of Briot-Bouquet Differential Equations

For equation (3), the character of the simplified equation depends on the value of $\lambda = f_y(0,0)$. We have the following four cases: (i) λ is neither 0 nor negative. A suitable formal transformation (7) changes (3) to

$$x dz/dx = \lambda z + bx^\lambda.$$

In particular, if λ is not equal to a positive integer, then $b=0$. The double power series (7) is uniformly convergent. There exists a function $\varphi(x, z)$ of (x, z) holomorphic at $(0,0)$ such that $y = \varphi(x, x^\lambda(b \log x + C))$ is a general solution of (3) with an integration constant C . (ii) $\lambda=0$. The equation satisfied by z takes the form

$$x dz/dx = z^{m+1}(b + b'z^m), \quad m \geq 1.$$

If $b=0$, b' necessarily vanishes and $x=0$ is a holomorphic point of (3). A general solution is given by

$$Z(x) = (C - mb \log x)^{-1/m}, \quad b \neq 0, \quad b' = 0,$$

and

$$Z(x) = \left(\frac{b'}{b} \alpha \left(\frac{mb^2}{b'} \log \frac{1}{x} + C \right) \right)^{-1/m}, \quad bb' \neq 0.$$

Here, $\zeta = \alpha(t)$ is the branch (of the inverse function of $\zeta - \log \zeta = t$) such that $\alpha(t) - t \log t - t \rightarrow 0$ as $t \rightarrow \infty$. Then there exists a holomorphic function $\varphi(x, z)$ of (x, z) for $|x| < \delta$, $|m \arg z + \arg b| < 3\pi/2 - \varepsilon$, $|z| < \Delta$ such that $\varphi(x, Z(x))$ is a general solution of (3). (iii) λ is a negative rational number $-\mu/\nu$. The equation satisfied by z is written as

$$\nu x dz/dx = z(-\mu + b(x^\mu z^\nu)^\mu + b'(x^\mu z^\nu)^{2\mu}).$$

A general solution has the form

$$Z(x) = x^\lambda (C - mb \log x)^{-1/m\nu}, \quad b' = 0,$$

and

$$Z(x) = x^\lambda \left(\frac{b'}{b} \alpha \left(\frac{\nu mb^2}{b'} \log \frac{1}{x} + C \right) \right)^{-1/m\nu},$$

$$bb' \neq 0.$$

In this case, there exists a holomorphic function $\varphi(x, z)$ of (x, z) for $|m\mu \arg x + m\nu \arg z + \arg b \mp \pi/2| < \pi - \varepsilon$, $|x| < \delta$, $|z| < \Delta$ such that $\varphi(x, Z(x))$ is a general solution of (3). M. Iwano expressed this solution in the form $\psi((x^\mu Z(x))^\mu, x, Z(x))$, where $\psi(w, x, z)$ is holomorphic for $|\arg w \mp \frac{\pi}{2}| < \pi - \varepsilon$, $0 < |w| < \delta$, $|x| < \Delta$, $|z| < \Delta$. In particular, if $b=b'=0$, $\varphi(x, z)$ is holomorphic at $(0,0)$. (iv) λ is a negative

irrational number. The equation in z has the form

$$x \, dz/dx = \lambda z.$$

The formal transformation (7) may either diverge or converge. Dulac proved that if (7) diverges and if there exists a solution $y(x)$ such that $y(x) \rightarrow 0$ as $x \rightarrow 0$ along a suitable path L , then $|x^\alpha y(x)^\beta \arg x| \rightarrow \infty$ and $|x^\alpha y(x)^\beta \arg y(x)| \rightarrow \infty$ as $x \rightarrow 0$, $x \in L$ for any α and β . However, the existence of such a solution is not yet verified. C. L. Siegel proved that if λ satisfies certain inequalities, the formal transformation (7) is divergent. An example such that (7) is divergent was first given by Dulac. A very simple example for such a case was given by Y. Sibuya.

In the case $f(0, 0) = 0$ and $\lambda = f_y(0, 0) \neq 0$ for (4), the most complete result was obtained by Hukuhara, namely: (i) A suitable formal transformation (7) reduces equation (4) to

$$x^{\sigma+1} \, dz/dx = z(\alpha_0 + \alpha_1 x + \dots + \alpha_n x^n), \quad \alpha_0 = \lambda.$$

A general solution is given by $Z(x) = C \cdot x^{\alpha_0} e^{\Lambda(x)}$, where $\Lambda(x)$ is a polynomial in $1/x$ of degree σ . (ii) A general solution of (4) is expressed by a uniformly convergent power series of the form $\sum \varphi_k(x) Z(x)^k$, where the $\varphi_k(x)$ are holomorphic functions of x for a certain sectorial neighborhood of $x=0$ and have asymptotic expansions $\sum p_{jk} x^k$ as $x \rightarrow 0$.

Assume $f_j(0, 0, \dots, 0) = 0$ for equations (5). Put $\lambda_{jk} = \partial f_j / \partial y_k(0, 0, \dots, 0)$. Denote by $\lambda_1, \dots, \lambda_n$ the eigenvalues of an $n \times n$ matrix with elements $\{\lambda_{jk}\}$. Then (i) if an angle ω can be chosen so that for some $m \leq n$, all of $|\omega|$, $|\arg \lambda_1 - \omega|, \dots, |\arg \lambda_m - \omega|$ are less than $\pi/2$, equations (5) possess solutions that are expressed as uniformly convergent $(m+1)$ -tuple power series of x , $Z_1(x), \dots, Z_m(x)$:

$$\sum p_{jk_0 k_1 \dots k_m} x^{k_0} Z_1^{k_1} \dots Z_m^{k_m}.$$

Here the $Z_k(x)$ are general solutions of the simplified equations and have the expression

$$Z_k(x) = x^{\lambda_k} (C_k + \text{a polynomial of } C_1, \dots, C_{k-1}, \log x), \quad k = 1, 2, \dots, m.$$

(ii) Moreover, Iwano extended the result of (i) as follows: When there exists one and only one zero among the other $n-m$ eigenvalues, equations (5) have solutions, depending on $m+1$ arbitrary constants, that are expressed as $(m+1)$ -tuple uniformly convergent power series

$$\sum p_{jk_0 k_1 \dots k_m} (Z_{m+1}(x)) x^{k_0} Z_1^{k_1} \dots Z_m^{k_m}.$$

Here the coefficients $p_{jk_0 k_1 \dots k_m}(z_{m+1})$ are holomorphic functions of z_{m+1} in a sectorial neighborhood of $z_{m+1} = 0$ and admit asymptotic expansions in powers of z_{m+1} as $z_{m+1} \rightarrow 0$. In this case, the functions $Z_1(x), \dots, Z_{m+1}(x)$ can-

not generally be integrated by quadratures, but as $Z_{m+1}(x) \rightarrow 0$, the power series expansions coincide with the expressions obtained in (i). (iii) In the case when the Jacobian matrix (λ_{jk}) is the zero matrix, Iwano constructed, under additional assumptions, a convergent analytic expression of a general solution for equations (5).

Let the right-hand side of (6) be holomorphic at $(0, 0, \dots, 0)$. In 1939 Trjitzinski proved the existence of solutions that admit asymptotic expansions in powers of n arbitrary constants. In 1940 and 1941, Malmquist proved, under strong conditions, the existence of solutions that are expressed as uniformly convergent power series of $Z_\alpha(x), \dots, Z_\beta(x)$: $\sum p_{jk_\alpha \dots k_\beta}(x) Z_\alpha(x)^{k_\alpha} \dots Z_\beta(x)^{k_\beta}$. Here the $Z_k(x)$ are polynomials of x and $\log x$ of the form

$$Z_k(x) = e^{\Lambda_k(x)} x^{\lambda_k} (C_k + \text{a polynomial of } C_{k-1}, \dots, C_\alpha, \log x), \quad k = \alpha, \dots, \beta,$$

where the coefficients admit asymptotic expansions in powers of x . Trjitzinski's result is contained in Malmquist's result as a special case. On the other hand, under much weaker assumptions than Malmquist's, Hukuhara solved a problem on the formal simplification of equations (6) and formal solutions. Iwano improved Hukuhara's result on formal solutions and discussed the convergence of formal solutions under weaker conditions than Malmquist's (*Ann. Mat. Pura Appl.*, 1957, 1959). The $p_{jk_\alpha \dots k_\beta}(x)$ are holomorphic functions of x in a sectorial neighborhood of $x=0$ and admit asymptotic expansions in powers of x as $x \rightarrow 0$. The angle of the sector in which the asymptotic expansions are valid is largest for Iwano's method.

If $\sum \sigma_j < n$, equations of the form

$$x^{\sigma_j} dy_j/dx = f_j(x, y_1, \dots, y_n), \quad j = 1, \dots, n,$$

possess at least $n - \sum \sigma_j$ solutions that are holomorphic for $|x| < \delta$ (R. W. Bass, *Amer. J. Math.*, 77 (1955)). This result is analogous to those obtained by O. Perron, F. Lettenmyer, and Hukuhara and Iwano in the linear case (\rightarrow 254 Linear Ordinary Differential Equations (Local Theory)).

E. Singular Perturbations

The terms on the right-hand side of the nonlinear differential equations

$$e^{\sigma_j} dy_j/dx = f_j(x, y_1, \dots, y_n, \varepsilon), \quad j = 1, 2, \dots, n, \quad (9)$$

are holomorphic functions of (x, y, ε) for $|x| < a$, $\|y\| < b$, $0 < |\varepsilon| < c$, $|\arg \varepsilon| < d$, and admit uniformly convergent expansions in powers of y with coefficients asymptotically developable in

powers of ε . The σ_j are nonnegative integers. W. R. Wasow, W. A. Harris, Sibuya, and Iwano and T. Saito discussed problems on constructing asymptotic or convergent expansions for bounded solutions that are dependent on several arbitrary constants.

In equations (9), the f_j and $\partial f_j / \partial y_k$ are continuous functions of (x, y, ε) for $-\infty < x < +\infty$, $\|y\| < b$, $|\varepsilon| < c$, and periodic functions of period T with respect to x . Moreover, assume that a system of degenerate algebraic equations

$$0 = f_j(x, y_1, \dots, y_n, 0), \quad j = 1, \dots, n, \quad (10)$$

has a periodic solution $y_j = p_j(x)$ of period T for $-\infty < x < +\infty$. Then if equations (9) have periodic solutions $y_j = p_j(x, \varepsilon)$ of period T such that $y_j \rightarrow p_j(x)$ as $\varepsilon \rightarrow 0$, the $p_j(x, \varepsilon)$ are called **singular perturbations** of $p_j(x)$ for equations (9). Concerning this problem, see I. M. Volk (*Prikl. Mat. Mekh. SSSR*, 10 (1946)). The work of Wasow (1950) on a single equation

$$\varepsilon^\sigma y^{(n)} = f(x, y, y', \dots, y^{(m)}, \varepsilon), \quad \sigma > 0, \quad n > m \geq 0, \quad (11)$$

is remarkable.

290 (XIII.11) Nonlinear Oscillation

A. General Remarks

By **nonlinear oscillation** we usually mean oscillation described by periodic or \dagger almost periodic solutions of nonlinear ordinary differential equations. The theory of nonlinear oscillation is sometimes called **nonlinear mechanics**. In connection with oscillations in \dagger dynamical systems and electrical circuits, the theory of nonlinear oscillation has been studied intensively in the Soviet Union under the direction

of N. M. Krylov and N. N. Bogolyubov since around 1930, and after World War II research in this field became active in Western countries also.

Written as first-order systems, the differential equations in this theory take one of the forms

$$dx/dt = X(x) \quad (1)$$

or

$$dx/dt = X(x, t), \quad (2)$$

where x is a vector and t is a scalar. A differential equation of the form (1) is said to be **autonomous**. In a differential equation of the form (2), $X(x, t)$ is usually assumed to be periodic or almost periodic in t . In the former case, the differential equation (2) is said to be **periodic**, and in the latter case, **almost periodic**. Oscillations in physical systems are described mostly by periodic or almost periodic differential equations; therefore it is a principal problem in the theory of nonlinear oscillation to find a periodic or almost periodic solution of these differential equations. However, an oscillation described by a solution of a differential equation can be actually realized only when the solution is \dagger stable (\rightarrow 394 Stability) under a small variation of the initial value. Therefore it is important to investigate the stability of periodic or almost periodic solutions. In view of the fact that an actual phenomenon may be only approximately described by mathematical equations, sometimes it is necessary to require a certain stability of the system so that solutions of a periodic or almost periodic equation stay stable under a small variation of the equation itself. Such stability is called **structural stability**, the investigation of which is also important.

It may happen that a differential equation possesses neither a periodic solution nor an almost periodic solution, but that it has an almost periodic \dagger integral manifold (i.e., a manifold $x = f(t, \theta)$ in tx -space, where θ is a parameter, such that $f(t, \theta)$ is periodic or almost periodic in t and periodic in θ) containing the \dagger trajectory of the differential equation passing through an arbitrary point of the manifold. In this case, we can consider that a solution corresponding to a trajectory lying on the manifold describes an oscillation. Therefore it is important to find a periodic or almost periodic integral manifold of a differential equation and to investigate the stability of such a manifold.

The methods used most frequently in research on nonlinear oscillation are: (i) geometric methods, (ii) analytic methods, and (iii) numerical methods.

B. Linear Oscillations

Let S_1 and S_1^* be the spaces of all ω -periodic solutions of the ω -periodic linear system

$$dx/dt = A(t)x, \quad A(t + \omega) = A(t), \quad (3)$$

and its adjoint system, respectively. Then the space P_ω of continuous ω -periodic functions $\mathbf{R} \rightarrow \mathbf{R}^n$ has direct sum decompositions $P_\omega = S_1 + S_2$ and $P_\omega = S_1^* + S_2^*$ so that $(\mathbf{x}, \mathbf{y}) = 0$ for every $\mathbf{x} \in S_1$, $\mathbf{y} \in S_2$ or $\mathbf{x} \in S_1^*$, $\mathbf{y} \in S_2^*$, where $(\mathbf{x}, \mathbf{y}) = (1/\omega) \int_0^\omega \mathbf{x}(s)\mathbf{y}(s)ds$. Let $\{\xi^1, \dots, \xi^m\}$ and $\{\eta^1, \dots, \eta^m\}$ (m may be 0) be bases of S_1 and S_1^* orthonormal with respect to (\cdot, \cdot) . Then for $\mathbf{p} \in P_\omega$ there is a unique ω -periodic solution \mathbf{x} of

$$dx/dt = A(t)x + \mathbf{p}(t) \quad (4)$$

belonging to S_2 under the condition $(\eta^k, \mathbf{p}) = 0$ ($k = 1, \dots, m$), which is represented in the form $\mathbf{x} = G[\mathbf{p}]$ by a bounded linear operator $G: P_\omega \rightarrow P_\omega$. Also, if (3) and hence its adjoint system have no nontrivial ω -periodic solution, then (4) always has a unique ω -periodic solution given by $\mathbf{x} = G[\mathbf{p}]$, and this is true even if the ω -periodicity is replaced by almost periodicity. The almost periodic system (3) is said to be **regular** if (4) has almost periodic solution for an arbitrary almost periodic function $\mathbf{p}(t)$. A necessary and sufficient condition for (3) to be regular is that (3) induce an **exponential dichotomy**, that is, the solution space S of (3) have a direct sum decomposition $S = S_- + S_+$ such that $\|\mathbf{x}(t)\| \leq M e^{-\gamma|t-s|} \|\mathbf{x}(s)\|$ holds for $-\infty < s \leq t < \infty$ if $\mathbf{x} \in S_+$ and for $-\infty < t \leq s < \infty$ if $\mathbf{x} \in S_-$, where M and γ are positive constants. An autonomous (resp. periodic) system (3) is regular if and only if no \dagger characteristic roots (resp. characteristic exponents) have zero real parts.

C. Geometric Methods

Geometric methods are used frequently for finding a periodic solution in an autonomous or periodic case. In the autonomous case (1), a periodic solution describes a closed orbit (t is a parameter of a curve) in \mathbf{x} -space, which is usually called a **phase space**. The geometric method is used to show the existence and the stability of a closed orbit by investigating geometrically the behavior of orbits in the phase space. In such an approach, the properties of \dagger critical points and \dagger limit sets (\rightarrow 126 Dynamical Systems) are utilized frequently. This method is effective especially for 2-dimensional cases on the basis of the \dagger Poincaré-Bendixson theorem, and various results are given for a generalized **Liénard's** (or **Duffing's**)

differential equation $\ddot{x} + f(x)\dot{x} + g(x) = 0$, which includes the **van der Pol differential equation** $\ddot{x} - \lambda(1 - x^2)\dot{x} + x = 0$ [1, 2].

In the periodic case (2), let $\omega (> 0)$ be a period of $\mathbf{X}(\mathbf{x}, t)$ with respect to t and $\mathbf{x} = \varphi(t, \alpha)$ be a solution of (2) such that $\varphi(0, \alpha) = \alpha$. Then a periodic solution of (2) is given by $\mathbf{x} = \varphi(t, \alpha_0)$, where α_0 satisfies $\varphi(\omega, \alpha_0) = \alpha_0$. Thus the existence of a periodic solution can be shown by investigating geometrically the existence of a \dagger fixed point of the mapping $\mathbf{x} \rightarrow \mathbf{x}' = \varphi(\omega, \mathbf{x})$ in the phase space. In such an approach, \dagger Brouwer's fixed-point theorem is utilized frequently. In the mapping $\mathbf{x} \rightarrow \mathbf{x}'$, it may happen that there is no fixed point but that there exists an \dagger invariant manifold. In this case, we get a periodic integral manifold.

Geometric methods give information on qualitative properties, but usually not on quantitative properties like the shape of an oscillation. Thus these methods are in general not sufficient for the analysis of the phenomena met in practice.

D. Analytic Methods

At present analytic methods are used most frequently in the study of nonlinear oscillations because, in comparison with geometric methods, they enable us to get many quantitative results in addition to the qualitative ones. However, these methods are usually efficient only for **weakly nonlinear differential equations**, that is, differential equations differing only slightly from linear differential equations (general nonlinear differential equations are called sometimes **strongly nonlinear differential equations**). In this sense, analytic methods are all \dagger perturbation methods in the wider sense [3], and the variety of the methods lies in the form of perturbation and the method of calculation. To make use of analytic methods, we always reduce the given differential equation to a differential equation of the form

$$\dot{\mathbf{x}} = A\mathbf{x} + \varepsilon \mathbf{X}(\mathbf{x}, t, \varepsilon). \quad (5)$$

Here ε is a parameter with small absolute value, A is a matrix of the form $A = \text{diag}(O_p, B)$, where O_p is a $p \times p$ zero matrix and B is a matrix whose eigenvalues have all nonzero real parts, and $\mathbf{X}(\mathbf{x}, t, \varepsilon)$ is periodic or almost periodic in t .

(i) When $\mathbf{X}(\mathbf{x}, t, \varepsilon)$ is periodic in t , Poincaré's perturbation method is used frequently.

(ii) In practical problems, we frequently meet the case $A = 0$, that is, the case where (5) is of the form

$$\dot{\mathbf{x}} = \varepsilon \mathbf{X}(\mathbf{x}, t, \varepsilon). \quad (6)$$

In this case, the **average** $X_0(\mathbf{x}, \varepsilon) = \lim_{T \rightarrow 0} (1/T) \int_0^T X(\mathbf{x}, t, \varepsilon) dt$ exists. If $dx/dt = X_0(\mathbf{x}, 0)$ has a periodic solution $\xi(t)$ and the related variational linear system is regular, then (6) has an (almost) periodic integral manifold $\mathbf{x} = \mathbf{f}_\varepsilon(t, \theta)$ such that $\mathbf{f}_\varepsilon(t, \theta) \rightarrow \xi(\theta)$ uniformly as $\varepsilon \rightarrow 0$. The **method of averaging** based on this fact was devised by Bogolyubov and Mitropol'skii [4] and is used frequently. The equation

$$\ddot{\mathbf{x}} + \omega^2 \mathbf{x} = \varepsilon f(\mathbf{x}, \dot{\mathbf{x}}, t, \varepsilon) \quad (7)$$

is one of the examples that can be reduced to an equation of the form (6). Equation (7) appears frequently in practical problems, and hence various convenient techniques are devised, such as the **method of linearization**, the **asymptotic method**, the **method of harmonic balance** [4], etc., through which we can apply the method of averaging directly to the given equation (7).

(iii) Consider an ω -periodic system

$$d\mathbf{x}/dt = A(t)\mathbf{x} + \mathbf{f}(\mathbf{x}, t). \quad (8)$$

For any $\mathbf{x}(t) \in P_\omega$, $d\mathbf{x}/dt = A(t)\mathbf{x} + \mathbf{f}(\mathbf{x}(t), t)$ is of the form (4) and it has an ω -periodic solution $\sum_{k=1}^m a_k \xi^k + G[N\mathbf{x}]$, or

$$T\mathbf{x} = \sum_{k=1}^m a_k \xi^k + G \left[N\mathbf{x} - \sum_{k=1}^m (\eta^k, N\mathbf{x}) \eta^k \right] \quad (9)$$

under the condition $(\eta^k, N\mathbf{x}) = 0$ ($k = 1, \dots, m$) as in Section B, where $N: P_\omega \rightarrow P_\omega$ is defined by $N\mathbf{x} = \mathbf{f}(\mathbf{x}(\cdot), \cdot)$, and the ω -periodic solutions of (8) correspond to the fixed points of the transformation $T: P_\omega \rightarrow P_\omega$ induced by (9), where the a_k in (9) are given by $a_k = (\xi^k, \mathbf{x})$, as is required when \mathbf{x} is a fixed point. This is the **alternative or bifurcation method** [6–9], which is extendable to the case of almost periodic systems under the regularity of (3) [10]. In order to obtain a fixed point of T , various kinds of fixed point theorems can be utilized.

(iv) In Section C and (iii) above, the search for a fixed point of an appropriate mapping is a principal device. However, the choice of a suitable domain for the mapping is a crucial problem, and usually an a priori bound for solutions is looked for. The concept of stability and hence Lyapunov's second method are effective in such situations [11].

E. Numerical Methods

Numerical methods are used for obtaining explicit forms of the oscillations. They are convenient in practical applications, since they can be used efficiently whether or not the nonlinearity of the system is weak. For an autonomous or periodic system, one can utilize the following methods as efficient means

of computing periodic solutions: **Newton's iterative method**, the **finite-element method**, the **Lindstedt-Poincaré method**, the **method of multiple scales**, the **method of harmonic balance**, the **Galerkin method**, etc. [12–15].

For weakly nonlinear cases, analytic methods (that is, perturbation methods) are very efficient. However, when a parameter is fixed beforehand, it is not easy to know whether the conclusion obtained by the perturbation method is valid for the given value. For strongly nonlinear cases, it is very difficult to analyze the problems by analytic methods, and at present hardly any efficient methods exist. Numerical methods will therefore become exceedingly important in research on nonlinear oscillations. These are now of tolerable efficiency and reliability, due to progress in high-speed machine computation.

F. Nonstationary Oscillations

Physically speaking, an oscillation is a stationary state. However, when a system contains a parameter varying slowly with time, the oscillation also varies slowly with time (for example, when the length of a pendulum varies slowly, the amplitude of the pendulum also varies slowly). Such variation of oscillations in the course of time is represented by $d\mathbf{x}/dt = \varepsilon f(\mathbf{x}, t, \varepsilon t, \varepsilon)$, where $\mathbf{f}(\mathbf{x}, t, s, \varepsilon)$ is (almost) periodic in t, s . Such cases provide important problems in the theory of nonlinear oscillations; one such problem has been posed by Mitropol'skii [16] under the name **nonstationary oscillations** and has been investigated by means of the method of multiple scales [15].

291 (XIII.12) Nonlinear Problems

A. General Remarks

Nonlinear problems deal with nonlinear mappings or operators and the related equations. Until recently it was customary to consider nonlinear problems as belonging to applied mathematics and the physical sciences. However, nonlinear problems now belong to modern mathematics. Many phenomena in mathematical physics are essentially described by nonlinear equations, e.g., the motions of several particles or of viscous or compressible fluids (\rightarrow 420 Three-Body Problem, 204 Hydrodynamical Equations). Some of these equations are approximated by linear equations only when the variables appearing in the equations are restricted to very small domains; they are treated by perturbation methods when the variables stay in comparatively small domains. If these requirements cannot be met and we have to deal with equations in which the variation of the variables are not negligible, nonlinear problems certainly arise.

The methods of solution of nonlinear problems are not as powerful or general as those for linear differential equations. For instance, the \dagger principle of superposition of solutions does not hold for nonlinear problems, and therefore Fourier methods are no longer applicable. Indeed, some nonlinear problems can

be dealt with only by means of very particular or ad hoc devices.

B. Methods Used in Nonlinear Problems

Consider a nonlinear equation

$$G(x)=0, \quad (1)$$

where G is a nonlinear mapping or operator of a subset S of a linear space X into itself. If we put $G=I-F$ (I is the identity), equation (1) becomes

$$x=F(x). \quad (2)$$

Then a solution of (2) is a fixed point of F .

Therefore fixed-point theorems of various kinds are useful for solving (2) (\rightarrow 286 Nonlinear Functional Analysis).

Let $x^{(0)} \in S$, and suppose that we can define $x^{(k)}$, $k=1, 2, \dots$, by

$$x^{(k)}=F(x^{(k-1)}), \quad k=1, 2, \dots$$

If F is continuous and the sequence $x^{(k)}$ converges to a point $x \in S$, then x is a fixed point of (2). Such a method of constructing an approximate sequence by iteration is called the **iterative method**. \dagger Newton's iterative process, given by

$$x^{(k)}=x^{(k-1)}-[G'(x^{(k-1)})]^{-1}G(x^{(k-1)}),$$

is one such method, where G' denotes the \dagger Fréchet derivative of G .

If X is an infinite-dimensional space, many concepts and methods of the theory of functional analysis can be used for a number of nonlinear problems (\rightarrow 286 Nonlinear Functional Analysis).

We note that there exist nonlinear transformations that change nonlinear equations into linear ones. For example, the \dagger hodograph method, which is often applied in hydrodynamics, consists of reducing a system of \dagger quasi-linear partial differential equations of the form

$$A_i(u, v)u_x + B_i(u, v)u_y + C_i(u, v)v_x + D_i(u, v)v_y = 0 \quad (i=1, 2)$$

to linear differential equations

$$A_i y_v - B_i x_v - C_i y_u + D_i x_u = 0 \quad (i=1, 2)$$

by means of the \dagger hodograph transformation, which changes the independent variables from x, y to u, v (\rightarrow 205 Hydrodynamics).

C. Nonlinear Algebraic and Transcendental Equations

Consider a system of equations

$$f_i(x_1, \dots, x_n)=0 \quad (i=1, \dots, n). \quad (3)$$

Newton's iterative process can be applied as follows. Starting with a point $x^{(0)} = (x_1^{(0)}, \dots, x_n^{(0)})$ lying near the desired solution, we define $x^{(k)} = (x_1^{(k)}, \dots, x_n^{(k)})$, $k = 1, 2, \dots$, by solving the system of equations

$$\sum_{i=1}^n \frac{\partial f_j}{\partial x_i} (x^{(k-1)}) (x_i^{(k)} - x_i^{(k-1)}) + f_j(x^{(k-1)}) = 0 \quad (j = 1, \dots, n).$$

Under some conditions the iteration $\{x^{(k)}\}$ converges to the solution (\rightarrow 301 Numerical Solution of Algebraic Equations).

If the system (3) is a real one, (3) is equivalent to $\sum f_i^2 = 0$. It is clear that a method of obtaining a minimum of a function $f(x_1, \dots, x_n)$ is applicable to solving $\sum f_i^2 = 0$. Taking a point $x^{(0)}$, we define

$$x^k = x^{(k-1)} - \lambda_{k-1} \nabla f(x^{(k-1)}), \quad k = 1, 2, \dots,$$

where $\nabla f = (\partial f / \partial x_1, \dots, \partial f / \partial x_n)$, and let λ_{k-1} satisfy

$$f(x^{(k-1)} - \lambda_{k-1} \nabla f(x^{(k-1)})) \leq f(x^{(k-1)} - \lambda \nabla f(x^{(k-1)})) \quad (\lambda \geq 0).$$

Under suitable assumptions, a subsequence $x^{(k_j)}$ converges to x such that $\nabla f(x) = 0$ and $f(x^{(k_j)})$ decreases monotonically to $f(x)$ [1].

Let f be a continuous mapping from a domain D of \mathbf{R}^n or \mathbf{C}^n into itself. Then for any $x^{(0)} \in D$, the iteration $x^{(k)}$ can always be defined by $x^{(k)} = f(x^{(k-1)})$. The problem of the behavior of $x^{(k)}$ is an interesting and important one in pure mathematics; recent work in the physical sciences is yielding many new concepts related to this problem (\rightarrow 126 Dynamical Systems, 433 Turbulence and Chaos).

D. Nonlinear Differential Equations

Consider a nonlinear system of ordinary differential equations

$$dx/dt = f(t, x) \quad (x \in \mathbf{R}^n).$$

The initial value problem with initial condition $x(\tau) = \xi$ is equivalent to the problem of solving the nonlinear integral equation

$$x(t) = \xi + \int_{\tau}^t f(s, x(s)) ds. \quad (4)$$

The solution of (4) is a fixed point of the operator $T: \varphi(t) \mapsto \xi + \int_{\tau}^t f(s, \varphi(s)) ds$ defined for a suitable function space. Therefore fixed-point theorems are applicable to T , and the iterative method for T is called the †method of successive approximation. Also the method of the †Cauchy polygon is useful (\rightarrow 316 Ordinary Differential Equations (Initial Value Problems)). These ideas are extended to an

abstract Cauchy problem,

$$du/dt = A(t)u \quad (t > 0), \quad u(+0) = a,$$

in a Banach space X , where $a \in X$ and $A(t)$ is a nonlinear operator (\rightarrow 286 Nonlinear Functional Analysis).

For extensive studies of nonlinear ordinary and partial differential equations \rightarrow 314 Ordinary Differential Equations (Asymptotic Behavior of Solutions), 290 Nonlinear Oscillation, 394 Stability, 321 Partial Differential Equations (Initial Value Problems), 323 Partial Differential Equations of Elliptic Type, 325 Partial Differential Equations of Hyperbolic Type.

Nonlinear differential equations of special types appear in many fields of pure and applied mathematics, e.g., the Monge-Ampère equation and the equation for minimal surfaces in differential geometry (\rightarrow 183 Global Analysis, 275 Minimal Submanifolds), and the Toda lattice equation and the Korteweg-de Vries equation in mathematical physics (\rightarrow 287 Nonlinear Lattice Dynamics, 387 Solitons).

E. Nonlinear Problems of Control Systems

The basic equation for a †control system in which the state of the controlled object can be represented by an n -vector x is given by the following system of differential equations [3]:

$$\dot{x} = Ax - \varphi(\sigma)b, \quad \dot{\xi} = \varphi(\sigma), \quad \sigma = c'x - \gamma\xi, \quad (5)$$

where \dot{x} and $\dot{\xi}$ stand for dx/dt and $d\xi/dt$, respectively, ξ is a scalar function representing the control, b, c are constant n -vectors, γ is a constant number, c' is the transpose of c , and A is a constant $n \times n$ matrix whose characteristic roots have negative real parts. Furthermore, we assume that when the control has no effect upon the system, x is determined by $\dot{x} = Ax$. The quantities under consideration are all real. Finally, the function $\varphi = \varphi(\sigma)$ is a scalar function characteristic of the control mechanism. Generally, φ is nonlinear in σ , and hence equation (5) is nonlinear. Normally we assume that φ has the following properties: (i) $\varphi(\sigma)$ is a real-valued continuous function on $(-\infty, \infty)$ with $\varphi(0) = 0$ and $\sigma\varphi(\sigma) > 0$ for $\sigma \neq 0$; (ii) $\int_0^{\pm\infty} \varphi(\sigma) d\sigma = +\infty$. We say that (5) is **absolutely stable** if

$$x(t) \rightarrow 0, \quad \xi(t) \rightarrow 0 \quad \text{as} \quad t \rightarrow +\infty$$

for any choice of φ subject to (i) and (ii) and for every solution of (5). In the study of control systems an important problem is to obtain a necessary and sufficient condition for the system to be absolutely stable. In this connection, we have the following result, due to M. V.

Popov: (5) is absolutely stable if there exists a nonnegative q such that

$$\operatorname{Re}\{(1+i\omega q)(c'(i\omega I - A)^{-1}b)\} + q\gamma \geq 0 \quad (6)$$

for any real ω , where I is the $n \times n$ identity matrix. Conversely, if the absolute stability of (5) is given by means of the \dagger Lyapunov function (\rightarrow 394 Stability)

$$V(x, \sigma) = x'Bx + \alpha\sigma^2 + \alpha f'x + \beta \int_0^\sigma \varphi(\sigma) d\sigma,$$

where B is a constant matrix and f is a constant vector, then there exists a nonnegative q for which (6) is satisfied for all real ω .

F. Nonlinear Equations in Applied Mathematics

Some examples of nonlinear problems are given here (\rightarrow also 205 Hydrodynamics; 318 Oscillations).

(1) The nonlinear \dagger differential-difference equation

$$du(t)/dt = (a - u(t-1))u(t)$$

is called the **Cherwell-Wright differential equation** [4]. Given the initial condition $u(t) = g(t)$ ($0 \leq t \leq 1$, $g(t)$ is a given continuous function), its solution is uniquely determined for $0 \leq t < \infty$. If $a \leq 0$ and $g(1) > 0$, then $u(t) \rightarrow 0$ as $t \rightarrow \infty$; if $a = 0$ and $g(1) < 0$, then $u(t) \rightarrow -\infty$ as $t \rightarrow \infty$. For $a > 0$, $u(t) \rightarrow -\infty$ as $t \rightarrow \infty$ if $g(1) < 0$, while $u(t)$ either approaches a monotonically ($0 < a \leq 1/e$) or oscillates (boundedly) around a ($a > 1/e$) if $g(1) > 0$. In particular, we have damping oscillations for $a \leq 3/2$, while oscillatory solutions without damping appear for $a > \pi/2$.

(2) If we regard a star as a gas sphere and assume the polytropic relation $p = K\rho^\gamma$ (K and γ are constants) between the pressure p and the density ρ at each point inside the star, then we have a differential equation of the second order that determines the density distribution. This equation constitutes the basis of the classical theory of the internal structure of the stars and is called **Emden's differential equation** or the **polytropic differential equation**. It reads:

$$(1/\xi^2)d(\xi^2 d\theta/d\xi)/d\xi = -\theta^n,$$

where $\gamma = 1 + 1/n$, $\rho = \lambda\theta^n$, $r = \alpha\xi$, $\alpha = ((n+1)K\lambda^{\gamma-2}/(4\pi G))^{1/2}$, with r the distance from the center, G the universal gravitational constant, and λ an arbitrary constant. The solution that satisfies the conditions $\theta = 1$ and $d\theta/d\xi = 1$ at $\xi = 0$ is called the **Lane-Emden function** of index n . Emden's equation is invariant under the transformation $\xi \rightarrow A\xi$, $\theta \rightarrow A^{-2/(n-1)}\theta$ (with A an arbitrary constant).

291 Ref.

Nonlinear Problems

Although Emden's equation can be reduced to an equation of the first order, it has not been possible to solve it analytically except for the cases $n=0, 1$, and 5 . For certain values of n between 0.5 and 6 , Emden gave numerical solutions, which were refined later by Green, D. H. Sadler, and D. C. Miller [5].

(3) **Caianiello's differential equations**, which describe the state of a network of neurons [6], are

$$x_i(t+\tau) = Y\left[\sum_j \sum_r a_{ij}^{(r)} x_j(t-r\tau) - \theta_i\right],$$

where the function $x_i(t)$ represents the state of the i th neuron at the time t and takes only the values 0 and 1 . The state of the system is to be considered at the discrete times $t=0, \tau, 2\tau, \dots$. The (real) coefficient $a_{ij}^{(r)}$ represents the weight of the effect of hysteresis in the relay process from the cell j to the cell i . The nonnegative integer θ_i is the threshold value of the cell i . $Y[x]$ is the unit step function that is equal to 1 for $x \geq 0$ and vanishes for $x < 0$.

(4) The following **Hodgkin-Huxley differential equation** arises in the study of conduction and excitation in nerve systems [7]:

$$\frac{\partial^2 V}{\partial x^2} = \frac{2r_0}{R_0} \left(C_0 \frac{\partial V}{\partial t} + g_1 m^3 h (V - V_1) + g_2 n^4 (V - V_2) + g_3 (V - V_3) \right),$$

$$\frac{\partial m}{\partial t} = -(\alpha_1(V) + \beta_1(V))m + \alpha_1(V),$$

$$\frac{\partial h}{\partial t} = -(\alpha_2(V) + \beta_2(V))h + \alpha_2(V),$$

$$\frac{\partial n}{\partial t} = -(\alpha_3(V) + \beta_3(V))n + \alpha_3(V),$$

where α_i, β_i ($1 \leq i \leq 3$) are given functions of V , and r_0, R_0, C_0, g_i, V_i ($1 \leq i \leq 3$) are constants. The unknown function V is sought in the domain $0 < x < \infty, 0 < t < \infty$, while the initial values of V, m, h, n , and the boundary value of V are given at $t=0$ and $x=0$, respectively.

292 (XIX.4) Nonlinear Programming

A. Problems

A nonlinear programming problem is a type of mathematical programming problem where it is required to minimize or maximize a nonlinear function $\theta(x)$ of n -vector variable x defined in a closed connected set X^0 with a set of linear or nonlinear constraints. Minimization or maximization of a continuously differentiable function $\theta(x)$ under the equality condition expressed by a set of continuously differentiable functions has been traditionally dealt with by the method of Lagrange multipliers. Hence a typical nonlinear programming problem is usually formulated as follows.

(NLP) Minimize $\theta(x)$ under the condition $\bar{x} \in X^0 \subset \mathbf{R}^n$ and $g_i(x) \leq 0$ for $i = 1, 2, \dots, m$.

Or, equivalently, determine the set of all x such that $\theta(\bar{x}) = \min_{x \in C} \theta(x)$, where $C = \{x | x \in X^0 \text{ and } g(x) \leq 0\}$.

Here we need only consider minimization, since maximization problems can be converted to minimization problems by virtue of the obvious relation $\max \theta = -\min(-\theta)$.

The set C is known as the **feasible region** or the **constraint set**, and \bar{x} is called an **optimal solution** or simply a solution. In many nonlinear programming problems X^0 is \mathbf{R}^n . If $X^0 = \mathbf{R}^n$ and θ and g are linear functions on \mathbf{R}^n , then the problem becomes a linear programming problem (\rightarrow 255 Linear Programming). The problem of minimizing a quadratic function subject to linear constraints is called the **quadratic programming problem** (\rightarrow 349 Quadratic Programming). If X^0 is a convex set, θ is convex (or concave), and the g_i are convex on X^0 , then the minimization (or maximization) problem is known as a **convex** (or **concave**) **programming problem**. Convex and concave functions are important in nonlinear programming, because they admit reasonably straightforward sufficient conditions for optimality and also because they constitute the only important class of functions for which

necessary optimality conditions can be given without the differentiability condition. Subject to suitable modifications, the method of Lagrange multipliers can also be applied to the solution of nonlinear programming problems.

The **Lagrangian function** ψ associated with the minimization problem (NLP) is defined by

$$\psi(x, u) = \theta(x) + u'g(x),$$

where $u = (u_1, \dots, u_m)$ and u' denotes the vector of Lagrange multipliers.

A pair (\bar{x}, \bar{u}) is called a **saddle point** of $\psi(x, u)$, provided $\bar{x} \in X^0$, $\bar{u} \in \mathbf{R}^m$, $\bar{u} \geq 0$, and $\psi(\bar{x}, u) \leq \psi(\bar{x}, \bar{u}) \leq \psi(x, \bar{u})$ for all $x \in X^0$ and all $u \in \mathbf{R}^m$ such that $u \geq 0$. It follows easily that:

(1) (H. Uzawa [18]) If (\bar{x}, \bar{u}) is a saddle point of $\psi(x, u)$, then \bar{x} is an optimal solution.

(2) (Kuhn and Tucker [11]) Assume that X^0 is open and convex, and that θ and g are differentiable and convex. If there exists a pair (\bar{x}, \bar{u}) such that

$$\nabla \theta(\bar{x}) + \bar{u}' \nabla g(\bar{x}) = 0, \quad \bar{x} \in C, \quad \bar{u}' g(\bar{x}) = 0, \quad \bar{u} \geq 0$$

(where $\nabla \theta(x)$ and $\nabla g(x)$ denote, respectively, the gradient vector of θ at x and the Jacobian matrix of g at x), then \bar{x} is an optimal solution.

B. Necessary Conditions for Optimality

In Section A sufficient conditions for optimality were given. Some necessary conditions are also known.

(3) When $\theta(x)$ is continuously differentiable and all the g_i are linear, that is, when the condition is expressed as $Ax \leq b$ and $x \geq 0$, where A is an $m \times n$ matrix and b an m -vector, \bar{x} is an optimal solution only if \bar{x} is an optimal solution of the following linear programming problem.

(LP⁰) Minimize $v'x$ under the condition that $Ax \leq b$, $x \geq 0$, where $v = \nabla \theta(\bar{x})$.

By applying the duality theorem of linear programming, it can be proved that there exists a vector $\bar{u} \geq 0$ such that

$$\nabla \varphi(\bar{x}, \bar{u}) = \nabla \theta(\bar{x}) + \bar{u}' A = 0.$$

(4) (F. John [9]) Assume that X^0 is open, and that θ and g are differentiable. Then, if \bar{x} is a solution of the problem (NLP), there exist $u_0 \geq 0$ and $\bar{u} \in \mathbf{R}^m$ such that

$$u_0 \nabla \theta(\bar{x}) + \bar{u}' \nabla g(\bar{x}) = 0,$$

$$g(\bar{x}) \leq 0, \quad \bar{u}' g(\bar{x}) = 0, \quad \bar{u} \geq 0.$$

Now we consider the following: The vector-valued function g is said to satisfy **Guignard's constraint qualification** at an inner point x of X^0 if any vector y satisfying the linear inequalities $\nabla g_i(x) \cdot y \leq 0$ for $i \in I = \{i | g_i(x) = 0\}$ is in the convex hull spanned by the vectors tangent to the set C at x .

(5) (Guignard [7]) Let X^0 be an open set, let \bar{x} be an optimal solution of (NLP), let θ and g be differentiable at \bar{x} , and assume that g satisfies the Guignard constraint qualification. Then there exists $\bar{u} \in \mathbf{R}^m$ such that $\nabla \theta(\bar{x}) + \bar{u}' \nabla g(\bar{x}) = 0$, $g(x) \leq 0$, and $\bar{u}' g(\bar{x}) = 0$, $\bar{u} \geq 0$.

Guignard's constraint qualification is satisfied if neither of the following conditions hold: (L) Vectors $g_i(x)$ for $i \in I$ are linearly independent.

(S) (Slater's constraint qualification) The g_i are convex and X^0 is a convex set; and there exists a vector x such that $g_i(x) < 0$ for all i . With convexity of θ and g_i , differentiability is not required:

(6) (Kuhn and Tucker [11]) Let X^0 be a convex set, let θ and g be convex on X^0 , and assume that g satisfies Slater's constraint qualification. If \bar{x} is an optimal solution, then there exists $\bar{u} \in \mathbf{R}^m$, $\bar{u} \geq 0$, such that $\bar{u}' g(\bar{x}) = 0$ and (\bar{x}, \bar{u}) is a saddle point of $\psi(x, u) = \theta(x) + u' g(x)$.

C. Sensitivity Analysis

Now consider the following class of problems.

(Pc) Minimize the function $\theta(x)$ under the condition that $g(x) \leq c$, where c is a real m -vector. We denote by \bar{x}_c the set of the solutions of the problem (Pc) and denote $\theta_c^* = \theta(\bar{x}_c)$, $\bar{x}_c \in \bar{X}_c$. Suppose that Guignard's condition is satisfied for each c and that the set of Lagrange multipliers Λ_c is nonempty. Then for any real vector a , we have

$$\inf a' u_c \leq \lim_{t \rightarrow 0} \frac{1}{t} (\theta_{c+ta}^* - \theta_c^*) \leq \sup a' u_c, \quad u_c \in \Lambda_c.$$

Therefore, if the Lagrange multiplier is uniquely determined for some c , then u_c represents the vector of the rates of increments of the objective function to the small increments of the components of the constraints vector. Hence the components of the Lagrange-multiplier vector are called the **imputed prices** or **shadow costs** of the constraints; these have important economic implications, especially when the objective function is expressed in terms of money or profits.

More generally, we can consider the following class of problems.

(GPc): Minimize the function $\theta(x, c)$ under the condition that $g(x, c) \leq 0$, where c is a real parameter.

Denote by $\bar{x}(c)$ and $u(c)$ the solution and the Lagrange multiplier of (GPc) corresponding to the parameter c , respectively, and let $\theta^*(c) = \theta(\bar{x}(c))$. Then under a set of regularity conditions we have

$$\nabla \theta^*(c) = \nabla_c \theta(x(c), c) + u(c)' \nabla_x g(x(c), c),$$

where ∇_c denotes the gradient of θ or g with respect to the parameter.

D. Duality

A **duality theorem** in mathematical programming is the statement of a certain relationship between two problems. This relationship has the following two aspects: (i) one problem is a constrained minimization problem and the other is a constrained maximization problem; (ii) the existence of a solution to one of these problems ensures the existence of a solution to the other, and in this case their respective values are equal.

Let $\psi(x, u)$ be the Lagrangian form of (NLP), and define $\omega(u) = \inf_{x \in X^0} \psi(x, u)$. Then we can state the following two problems.

(P) (primary problem) Minimize $\theta(x)$ under the condition that $x \in X^0$ and $g(x) \leq 0$

(D) (dual problem) Maximize $\omega(u)$ under the condition $u \geq 0$.

If (\bar{x}, \bar{u}) gives a saddle point of $\psi(x, u)$, then

$$\inf \theta(x) = \theta(\bar{x}) = \sup \omega(u) = \omega(\bar{u}) = \psi(\bar{x}, \bar{u}).$$

The dual problem can be formulated alternatively as follows.

(\tilde{D}) Maximize $\psi(x, u) = \theta(x) + u' g(x)$ subject to $(x, u) \in Y = \{(x, u) | x \in X^0, u \in \mathbf{R}^m, u \geq 0, \nabla_x \psi(x, u) = 0\}$ (where $\nabla_x \psi(x, u)$ denotes the vector whose components are the partial derivatives $\partial \psi(x, u) / \partial x_i$ for $i = 1, \dots, n$).

There are a number of duality theorems related to problems (P) and (\tilde{D}); two such theorems are as follows:

(1) (P. Wolfe [20]) Suppose that X^0 is open and convex, that θ and g are differentiable and convex, and that g satisfies the Kuhn-Tucker constraint qualification. Then, if \bar{x} is a solution of (P), there exists a $\bar{u} \in \mathbf{R}^m$ such that (\bar{x}, \bar{u}) is a solution of (\tilde{D}) and $\theta(\bar{x}) = \psi(\bar{x}, \bar{u})$.

(2) (O. L. Mangasarian and J. Ponsstein [13]) Suppose that X^0 is open and convex, that θ and g are differentiable and convex, and that (\hat{x}, \hat{u}) is a solution of (\tilde{D}). If $\psi(x, u)$ is strictly convex in some neighborhood of \hat{x} , then \hat{x} is a solution of (P) and $\theta(\hat{x}) = \psi(\hat{x}, \hat{u})$.

The above two problems (P) and (D) are not symmetric. The notion of symmetric duality was introduced by G. B. Dantzig, E. Eisenberg, and R. W. Cottle:

Primary: Minimize

$$F(x, u) = K(x, u) - u' \nabla_u K(x, u),$$

subject to the constraints

$$\nabla_u K(x, u) \leq 0, \quad x \geq 0, \quad \text{and } u \geq 0;$$

Dual: Maximize

$$G(x, u) = K(x, u) - x' \nabla_x K(x, u),$$

subject to the constraints

$$\nabla_x K(x, u) \geq 0, \quad x \geq 0, \quad \text{and } u \geq 0,$$

where K is continuously differentiable in $(x, u) \in \mathbf{R}^n \times \mathbf{R}^m$.

(3) Dantzig et al. proved [6] the existence of a common optimal solution (\bar{x}, \bar{u}) to both the primary and dual problems, provided (i) an optimal solution (\bar{x}, \bar{u}) to the primary problem exists, (ii) K is convex in x for each u and concave in u for each x , and (iii) K is twice differentiable and the matrix of second partials $(\partial^2 K / \partial u^i \partial u^j)$ is negative definite at (\bar{x}, \bar{u}) .

Rockafellar [15] gave another expression of the duality relation: Define $F(x, y) = \theta(x)$ if $g(x) \leq y$ and $= \infty$ otherwise, and denote $\varphi(y) = \inf_{x \in X^0} F(x, y)$. Then $\theta(x) = \varphi(0)$. For any nonlinear function $\varphi(y)$, the conjugate $\varphi^*(\eta)$ is defined by

$$\varphi^*(\eta) = \sup_y (\eta'y - \varphi(y)).$$

(4) (Rockafellar [15]) $\sup \omega(u) = \varphi^{**}(0) = \text{clco } \varphi(0)$, where $\text{clco } \varphi(y)$ denotes the closed convex hull or maximum convex minorant of $\varphi(y)$ defined by $\text{clco } \varphi(y) = \sup_i 1'y \{1'z \leq \varphi(z) \text{ for all } z\}$. It follows from the above that $\inf \theta(x) = \sup \omega(u)$ if and only if $\varphi(0) = \text{clco } \varphi(0)$, which holds true if $\varphi(y)$ is convex.

Further forms of the duality theorem hold for linear or quadratic programming problems (\rightarrow 255 Linear Programming, 349 Quadratic Programming).

E. Algorithms

In a limited class of problems, i.e., when the objective function is quadratic and the constraints are linear (\rightarrow 349 Quadratic Programming) the optimal solution can be obtained by solving a system of linear equations by the simplex method or other algorithms; but in most nonlinear programming the solution is calculated by some kind of iterative procedure. Note that even when the constraints are given as equalities and all the functions involved are continuously differentiable, so that the optimal solution is explicitly given as a solution of a set of simultaneous equations, we usually require some iteration procedure, such as the Newton-Raphson algorithm, to obtain numerically the solution with preassigned accuracy; and the iteration is not always easy if the functions are sufficiently complex.

Several iterative procedures for solving nonlinear programming problems have been proposed. Since the simplex method is a powerful tool in linear programming, one type of approach is to obtain an approximately optimal solution by approximating the objective and the constraint functions by piecewise linear functions and then applying linear programming techniques to get the approximately optimal solution within each region. Another

is to change the constrained problem to a nonconstrained one by introducing a sufficiently large number M , called the penalty, and then maximizing

$$\theta_M(x) = \theta(x) + M \sum_j \max(g_j(x), 0)$$

without the constraint. This is called the **penalty method**.

The third and most generally applicable technique is the **gradient method**, of which several variations are known:

(i) **Arrow-Hurwicz-Uzawa gradient method** [4]. Concave or convex programming problems can be solved by finding a saddle point of the Lagrangian function $\psi(x, u)$. Let $\varphi(x, u)$ be strictly concave and of class C^2 in n -vector $x \geq 0$ and convex and of class C^2 in m -vector $u \geq 0$ and possess a saddle point (\bar{x}, \bar{u}) . To approach a saddle point of $\varphi(x, u)$ it is natural to devise a gradient process of the form

$$\frac{dx_i}{dt} = \frac{\partial \varphi}{\partial x_i}, \quad \frac{du_j}{dt} = -\frac{\partial \varphi}{\partial u_j}. \quad (1)$$

To keep the variables in the positive orthant, we need to modify (1), and we consider the following system of differential equations:

$$\frac{dx_i}{dt} = \begin{cases} 0 & \text{if } x_i = 0 \text{ and } \frac{\partial \varphi}{\partial x_i} < 0 \\ \frac{\partial \varphi}{\partial x_i} & \text{otherwise} \end{cases} \quad (i = 1, \dots, n),$$

$$\frac{du_j}{dt} = \begin{cases} 0 & \text{if } u_j = 0 \text{ and } \frac{\partial \varphi}{\partial u_j} > 0 \\ -\frac{\partial \varphi}{\partial u_j} & \text{otherwise} \end{cases} \quad (j = 1, \dots, m).$$

Under certain regularity hypotheses, there exists a unique solution $(x(t), u(t))$ of the system with any initial point (x^0, u^0) , and the x component $x(t)$ of the solution converges to \bar{x} as $t \rightarrow \infty$.

Applying the above results to the Lagrangian function $\psi(x, u)$ we can solve the concave or convex programming problem.

(ii) **Rosen's gradient projection method** [16]. If a point x^0 of the feasible region does not give a solution for the minimization problem (P), then we look for a feasible point with a lower function value by proceeding from x^0 in the direction of the gradient of the function $-\theta(x)$. The method fails if x^0 is a boundary point and if the gradient vector points toward the exterior of the feasible region. Rosen's method [16] is to project the gradient onto the boundary of the feasible region and then proceed in the direction of this projection. In this manner, we remain on the boundary of the feasible region.

(iii) **Methods of feasible directions.** These were first described by G. Zoutendijk [21].

Consider the problem of minimizing $\theta(x)$ subject to the constraint $x \in S \subset \mathbb{R}^n$, where S is a closed, connected set satisfying certain regularity conditions and θ is a continuously differentiable function of the n -vector x , such that, for some α , the set $\{x \in S \mid \theta(x) \leq \alpha\}$ is bounded and nonempty.

A method of feasible directions is any recipe for solving this problem by proceeding along the following lines: (1) Start with some $x^0 \in S$ such that $\theta(x^0) < \sup \alpha$. (2) Pass from the k th iteration point x^k to x^{k+1} by first determining a direction s^k in x^k such that the ray $x^k + \lambda s^k$ lies in S for all sufficiently small $\lambda > 0$. (3) Then determine the step length λ_k , thus obtaining the $(k+1)$ st iterate $x^{k+1} = x^k + \lambda_k s^k$. (4) Repeat this procedure until some prescribed stopping condition is satisfied.

There are many methods of determining the s^k , and in most cases the λ_k are then determined by solving a one-dimensional minimum problem along the direction so obtained. Zoutendijk has unified the various possible methods of feasible directions and the relevant normalization rules that yield the optimal directions s^k , and has investigated this subject in detail from the viewpoint of computational technique [21, 22].

F. Generalizations

The extension of the Kuhn-Tucker theory to linear topological spaces is due to L. Hurwicz [8]. Let \mathcal{X} be a linear space, \mathcal{Y}, \mathcal{Z} be linear topological spaces, P_Y, P_Z the nonnegativity cones of \mathcal{Y}, \mathcal{Z} , respectively, which are closed convex cones containing inner points, D a convex set in \mathcal{X} , and F, G concave mappings (\rightarrow 88 Convex Analysis A) from D into \mathcal{Y}, \mathcal{Z} , respectively, such that $G(D)$ contains an inner point of P_Z . If $F(X)$ attains its maximal point when $X = X_0$ and X_0 satisfies $G(X_0) \geq 0, X_0 \in D$, then there exist $Y_0^* \geq 0, Z_0^* \geq 0$ such that $\Phi(X, Z^*) = Y_0^*(F(X)) + Z_0^*(G(X))$ has a saddle point at (X_0, Z_0^*) . The condition that P_Y and P_Z have inner points can be weakened to cover the cases of $(l_p), (L_p), (s), (S)$ (Hurwicz and Uzawa). P. P. Varaiya [19] considered the following nonlinear programming problem in Banach space.

(B) Maximize $f(x)$ subject to $x \in A, g(x) \in A_Y$, where X, Y are real Banach spaces, $x \in X, g: X \rightarrow Y$ is a Fréchet differentiable mapping, f is a real-valued differentiable function, A is a subset of X , and A_Y is a convex set in Y .

The main results are similar to the Kuhn-Tucker necessary conditions. Varaiya also exhibited a saddle value problem related to

(B), when A_Y is a closed convex cone. L. W. Neustadt [14] investigated nonlinear programming problems in linear vector spaces and gave an application to the theory of optimal control. The main results are: (i) Kuhn-Tucker type conditions which are both necessary and sufficient for optimality, (ii) a duality theory for obtaining multipliers in the generalized Kuhn-Tucker conditions, and (iii) an application to optimal control theory.

293 (I.7) Nonstandard Analysis

A. General Remarks

Nonstandard analysis is a new field of research that has branched off from model theory and that provides a powerful method applicable in almost all fields of mathematical science.

About 1960, A. Robinson successfully used a nonstandard model of the real number field \mathbf{R} to justify Leibniz-type infinitesimal calculus. After this, using higher-order logic, he developed a stronger theory of nonstandard analysis, and applied it to other mathematical fields [1].

In this article, we adopt a first-order logic over a universe. In the final section we present a theory called nonstandard set theory; this is a conservative extension of Zermelo-Fraenkel set theory with the axiom of choice.

B. Axioms for Nonstandard Analysis

A nonempty set U is called a universe if the following four conditions are satisfied:

- (a) $x \in U, y \in x \Rightarrow y \in U$;
- (b) $x, y \in U \Rightarrow \{x, y\} \in U$;
- (c) $x \in U \Rightarrow \bigcup x \in U$;
- (d) $x \in U \Rightarrow \mathbf{P}(x) \in U$.

In what follows, U will be a universe containing the field \mathbf{R} of real numbers.

We construct a language \mathcal{L} describing mathematics in U . The alphabet consists of the

following symbols: (1) countably many variables. (2) constants corresponding to all elements in U . (3) predicate symbols $=$ and \in . (4) logical symbols $\neg, \wedge, \vee, \rightarrow, \exists, \forall$. (5) auxiliary symbols $[,]$. The last two symbols will be omitted where there is no danger of confusion.

Definition of formulas. (1) If t and s are terms (variables or constants), then $t = s$ and $t \in s$ are formulas (atomic formulas). (2) If ϕ and ψ are formulas, then $\neg\phi, \phi \wedge \psi, \phi \vee \psi, \phi \rightarrow \psi$ are formulas. (3) If ϕ is a formula and x is a variable, then $\exists x[\phi]$ and $\forall x[\phi]$ are formulas. (4) The formulas are those that can be constructed by the above procedure.

A formula ϕ containing at most n free variables is called an n -ary formula. In this case, we often write $\phi(x_1, \dots, x_n)$ for ϕ . A sentence is a 0-ary formula. We write $\models \phi$ if a sentence ϕ is true under the usual interpretation.

Consider a quadruple $(U, *U, *e, *)$ where $*U$ is a set, $*e$ is a binary relation on $*U$, and $*$ is a mapping: $a \mapsto *a$ from U to $*U$. An element α of $*U$ is called **standard** if $\alpha = *a$ for some $a \in U$, and **nonstandard** if not. Adjoin to \mathcal{L} constants representing all nonstandard elements of $*U$. Then we have a language $*\mathcal{L}$ for $*U$. A sentence in \mathcal{L} is a sentence in $*\mathcal{L}$. Taking $*U$ as the scope of quantifiers, we can interpret every $*\mathcal{L}$ -sentence in $*U$. We write $*\models \phi$ if an $*\mathcal{L}$ -sentence ϕ is true under this interpretation.

Axiom 1 (transfer): For every sentence ϕ in \mathcal{L} , we have

$$\models \phi \Leftrightarrow *\models \phi.$$

Definition: Let $\phi(x, y)$ be a binary formula in \mathcal{L} (resp. in $*\mathcal{L}$). We say that $\phi(x, y)$ is **concurrent** in U (resp. in $*U$), if, for every finite number of elements a_1, \dots, a_n in U (resp. in $*U$), there exists an element b in U (resp. in $*U$) such that $\models \phi(a_i, b)$ (resp. $*\models \phi(a_i, b)$) for $1 \leq i \leq n$.

Axiom 2 (enlargement): If a binary formula $\phi(x, y)$ in \mathcal{L} is concurrent in U , there exists an element β in $*U$ such that $*\models \phi(a, \beta)$ for all a in U .

A quadruple $(U, *U, *e, *)$ or simply $*U$ is called an **enlargement** of U if it satisfies Axioms 1 and 2.

These axioms are strong enough to develop the basic theory of nonstandard analysis, but sometimes we require a stronger axiom. Let κ be an infinite cardinal.

Axiom 3 (κ -saturation): Let $\phi(x, y)$ be a binary $*\mathcal{L}$ -formula concurrent in $*U$. Then, for every subset A of $*U$ with cardinality at most κ , there exists an element β of $*U$ such that $*\models \phi(\alpha, \beta)$ for all $\alpha \in A$.

$*U$ is called a **κ -saturated model** if it satisfies Axioms 1 and 3, and a **κ -saturated enlarge-**

ment if it satisfies Axioms 1, 2, and 3. If κ is not less than the cardinality of U , then a κ -saturated model is necessarily an enlargement.

In the remainder of this article, *U will be an enlargement of U , if the contrary is not explicitly mentioned.

For α in *U , $\hat{\alpha}$ is the set of $\xi \in ^*U$ such that $\xi^* \in \alpha: \hat{\alpha} = \{\xi \in ^*U \mid \xi^* \in \alpha\}$. For simplicity, we write \in for $^*\in$ and identify $\hat{\alpha}$ with α . Under this identification, a subset A of *U is called **internal** if it belongs to *U and **external** if not.

Axiom 1 and 2 imply the following results.

- (1) There exist infinite hypernatural numbers, namely, elements of $^*\mathbb{N}$ bigger than all $^*n, n \in \mathbb{N}$.
- (2) There are positive infinitesimal hyperreal numbers.
- (3) For every set A in U , there exists a hyperfinite internal subset of *A containing all $^*a, a \in A$. Here, Γ is called **hyperfinite** if we have $^*\models \phi(\Gamma)$, where $\phi(x)$ is a formula that says “ x is a finite set.”

- (4) Let A be a set in U . Then *A has non-standard elements if and only if A is an infinite set.

- (5) If a family \mathcal{F} of sets in U has the finite intersection property, then the family $\{^*A \mid A \in \mathcal{F}\}$ in *U has a nonempty intersection.

- (6) Let $\alpha: ^*\mathbb{N} \rightarrow ^*\mathbb{R}$ be an internal hypersequence. If $\alpha(^*n)$ is infinitesimal for every $n \in \mathbb{N}$, then there exists an infinite hypernatural number λ such that $\alpha(v)$ is infinitesimal for every hypernatural number v less than λ .

If we moreover assume Axiom 3, we have the following results.

- (7) The cardinality of an internal set is either finite or more than κ .

- (8) If a family \mathcal{F} of internal sets in *U has the finite intersection property and cardinality κ at most, \mathcal{F} has a nonempty intersection.

- (9) Introduce the order topology in $^*\mathbb{R}$. Then every subset of $^*\mathbb{R}$ with cardinality at most κ is bounded and discrete.

- (10) Let α, β be internal sets and C a subset of α with cardinality at most κ . Then every mapping from C to β can be prolonged to an internal mapping from α to β .

- (10') In particular, every external sequence $\mathbb{N} \rightarrow \beta$ can be prolonged to an internal sequence $^*\mathbb{N} \rightarrow \beta$. This follows from the assumption of countable saturation. This fact plays an essential role in nonstandard probability theory, which is now in the process of rapid development (\rightarrow Section D (3)).

C. Construction of Ultrapower Models

Let I be an infinite set. A mapping α from I to U is a family of elements in U with indices in I . So we write $\langle \alpha(i) \rangle_{i \in I}$ or simply $\langle \alpha(i) \rangle$ for α .

Let \mathcal{F} be a nonprincipal ultrafilter on I and define an equivalence relation $\sim_{\mathcal{F}}$ on the set U^I of all mappings from I to U :

$$\langle \alpha(i) \rangle \sim_{\mathcal{F}} \langle \beta(i) \rangle \Leftrightarrow \{i \in I \mid \alpha(i) = \beta(i)\} \in \mathcal{F}.$$

Denote by *U the quotient set of U under the relation $\sim_{\mathcal{F}}$. The class of $\langle \alpha(i) \rangle_{i \in I}$ will be denoted by $[\alpha(i)]_{i \in I}$ or simply $[\alpha(i)]$.

Define a binary relation $^*\in$ on *U :

$$[\alpha(i)]^* \in [\beta(i)] \Leftrightarrow \{i \in I \mid \alpha(i) \in \beta(i)\} \in \mathcal{F}.$$

Let $*$ be the diagonal mapping from U to *U and consider the quadruple $(U, ^*U, ^*\in, *)$.

Theorem (Łoś): The foregoing quadruple satisfies Axiom 1. Moreover, *U is a countably saturated model.

In particular, let I be the set of all finite subsets of U . For $i \in I$, put $\mu(i) = \{j \in I \mid i \subset j\}$. Then the family of sets $\mathcal{B} = \{\mu(i) \mid i \in I\}$ has the finite intersection property, and therefore there exists an ultrafilter \mathcal{F} on I including \mathcal{B} (use $^*\text{Zorn's lemma}$). If we construct *U from the ultrafilter \mathcal{F} , then *U is a countably saturated enlargement of U [1].

It is not easy to construct a κ -saturated enlargement for an arbitrary cardinal κ . We have two ways: to use a κ -good ultrafilter (the proof of its existence is difficult) [2, 3] or to use an ultralimit (iteration of ultrapowers) [4, 16].

D. Applications

(1) Infinitesimal Calculus. A hyperreal number α (element of $^*\mathbb{R}$) is called **infinitesimal** if $|\alpha|$ is smaller than every positive real number. If $\alpha - \beta$ is infinitesimal, α and β are said to be infinitely close to each other; this is written $\alpha \approx \beta$. If $1/\alpha$ is not infinitesimal, α is called finite. Every finite hyperreal number α is infinitely close to a real number a (completeness of \mathbb{R}). We call a the **standard part** of α and write $\text{st}(\alpha)$. Every finite hyperinteger is an integer.

Let f be a real-valued function on a real interval I . Then *f is a hyperreal-valued function on the hyperreal interval *I . The function f is continuous if and only if $f(x) \approx ^*f(\eta)$ for every $x \in I, \eta \in ^*I$ with $x \approx \eta$. The function f is uniformly continuous if $^*f(\xi) \approx ^*f(\eta)$ for every $\xi, \eta \in ^*I$ with $\xi \approx \eta$.

Let δx be a variable ranging over nonzero infinitesimals. The function $\delta f = ^*f(a + \delta x) - f(a)$ of δx will be called the infinitesimal increment of f at a . f is differentiable at a if and only if the quotient $\delta f / \delta x$ is of infinitesimal variation. The common standard part of $\delta f / \delta x$ is the derivative $f'(a)$.

The higher-order differential $\delta^n f$ is also justified as a higher-order infinitesimal difference, with the standard part of $\delta^n f / \delta x^n$ being

$f^{(n)}(a)$. We can define the Riemann integral as the standard part of a Riemann hypersum with respect to a hyperfinite partition of infinitesimal width.

This type of reformulation permits us to rewrite the whole of calculus, and many teachers are trying to adapt this theory to elementary calculus [5, 6].

(2) Topological Spaces. Let X be a topological space in U and let a be a point of X . The intersection of $*A$, A varying over the neighborhoods of a is called the **monad** of a and is denoted by $\text{Mon}(a)$. There exist hyperneighborhoods of a contained in $\text{Mon}(a)$ (infinitesimal neighborhoods). The topology is determined by the system of monads $\langle \text{Mon}(a) \rangle_{a \in X}$. We can thus rewrite the theory of topological spaces. For example, X is Hausdorff if and only if $\text{Mon}(a) \cap \text{Mon}(b) = \emptyset$ for every $a \neq b$ in X . X is compact if and only if every point of $*X$ belongs to the monad of some element in X . This characterization is very useful; using it, Robinson and Bernstein were able to solve the invariant subspace problem for a special class of operators on a Hilbert space [7]. We can also construct a Haar measure very naturally and simply [2].

(3) Measures and Probability Theory. Let (X, \mathbf{B}, m) be a measure space. Then there exist a hyperfinite subset Γ of $*X$ and a positive hyperreal-valued internal function φ such that we have

$$\int_X f \, dm = \sum_{\xi \in \Gamma} {}^*f(\xi) \varphi(\xi)$$

for every integrable function f [8]. The right-hand side is a hyperfinite sum. It follows that the measure m can be extended to a finitely additive measure defined over all subsets of X .

If in particular every measurable finite set is of measure 0, then there exist a hyperfinite subset Γ of $*X$ including X and a hypernatural number ρ such that we have

$$\int_X f \, dm \approx \frac{1}{\rho} \sum_{\xi \in \Gamma} {}^*f(\xi)$$

for every integrable function f [8]. If $m(X) = 1$, then ρ can be taken as the hypercardinality of Γ . Here, the right-hand side is nothing but the mean value of $*f$ on a hyperfinite set. This idea leads us to a simple description of probability theory.

The above method is rather formal; but P. Loeb [9] has pioneered a new approach in probability theory by constructing an external measure space from a hyperfinitely additive internal measure space (X, \mathcal{A}, ν) in $*U$. In the following, $*U$ is supposed to be countably saturated.

Let $\sigma(\mathcal{A})$ be the external countably additive algebra of subsets of X generated by \mathcal{A} . Then the mapping $\mathcal{A} \mapsto \text{st}(\nu(\mathcal{A}))$ from \mathcal{A} to \mathbf{R} can be extended to a measure on $\sigma(\mathcal{A})$. The completion of this measure space is denoted $(X, L(\mathcal{A}), L(\nu))$. In cases where X is hyperfinite, \mathcal{A} is the totality of internal subsets of X , and $\nu(X) = 1$, then the space $(X, L(\mathcal{A}), L(\nu))$ is called a **Loeb space** and $L(\nu)$ a **Loeb measure**.

Every Radon probability space can be represented as the image of a Loeb space by a measure-preserving mapping. Therefore the probability theory on a Radon probability space can be reduced to that on a Loeb space.

For example, for t Lebesgue measure on the interval $[0, 1]$, take an infinite hypernatural number λ and put $X = \{\mu/\lambda \mid \mu \in {}^*\mathbf{N}, 0 \leq \mu \leq \lambda - 1\}$. If we assign $1/\lambda$ to every point of X , we have an internal probability measure ν on X . Then the mapping $\text{st}: x \mapsto \text{st}(x)$ from X to $[0, 1]$ serves as a measure-preserving mapping from the Loeb space $(X, L(\mathcal{A}), L(\nu))$ onto the Lebesgue measure space on $[0, 1]$.

The notion of **lifting** plays a key role in probability theory on Loeb spaces. Let f be a real-valued function on X , and F an internal hyperreal-valued function on X . F is called a lifting of f if we have $f(x) = \text{st}(F(x))$ almost everywhere with respect to $L(\nu)$. Hence f is measurable if and only if it has a lifting.

Shuttling between an internal probability space and its Loeb space by lifting and standard-part mapping, we can develop, simply and partially hyperfinitely, probability theory on the Loeb space. Among others, Anderson [10, 11] and Keisler [12] applied this method quite successfully to Brownian motions, Itô integrals, stochastic differential equations, etc. [17].

E. Nonstandard Set Theory

In our formulation in \mathbf{B} , we must construct $*U$ from a fixed universe U . Nelson [13], Hrbacek [14] and Čuda [15] independently invented theories that nonstandardize the whole of set theory. In these theories, there is only one real number field \mathbf{R} , and \mathbf{R} already contains infinitesimal numbers. Compare this to Robinson-type infinitesimal analysis, where infinitesimal numbers are introduced as an ad hoc tool. The new theories may demand a reflection on mathematical description in the natural sciences.

In the following, we outline (intuitively) Hrbacek's theory, as strengthened and improved by Kawai [16].

We start from ZFC, the Zermelo-Fraenkel set theory plus the axiom of choice. The language of Kawai's theory NST is that of ZFC

plus two constants S and I . We understand S as the totality of standard sets and I as the totality of internal sets.

Let ϕ be a formula of ZFC, that is, a formula of NST without S and I . We write $^S\phi$ (resp. $^I\phi$), the formula of NST obtained by restricting the scope of variables in ϕ to S (resp. I).

The mathematical axioms and axiom schemes of NST are substantially as follows.

(1) If ϕ is an axiom of ZFC, then $^S\phi$ is an axiom of NST. In other words, all the axioms of ZFC are valid in the universe of standard sets.

(2) In the universe of all sets, all the axioms of ZFC are valid except the regularity axiom.

(3) Every standard set is internal. Every element of an internal set is internal.

(4) (transfer) For every n -ary formula $\phi(x_1, \dots, x_n)$ of ZFC, we have

$$\forall x_1 \in S \dots \forall x_n \in S [^S\phi(x_1, \dots, x_n) \leftrightarrow ^I\phi(x_1, \dots, x_n)].$$

(5) (saturation) For every set of size at most that of S , the scheme corresponding to Axiom 3 (κ -saturation) in Section B holds. Therefore the scheme corresponding to Axiom 2 (enlargement) holds also.

(6) (standardization) For every set a included in a standard set, there exists a standard set b such that we have $\forall x \in S [x \in a \leftrightarrow x \in b]$.

This completes the description of NST.

Theorem (Nelson-Hrbacek-Kawai): NST is a conservative extension of ZFC. That is, let ϕ be a sentence of ZFC. If $^S\phi$ can be proved in NST, then ϕ can be proved in ZFC.

Corollary: If ZFC is consistent, so is NST.

294 (II.9) Numbers

A. General Remarks

From counting, a primitive mental activity, came the **natural numbers** (\mathbf{N}) (\rightarrow Section B), which serve to denote the number of items or the order in which these items are arranged. We can extend this concept to define, step by step, the $^*\text{integers}$ (\mathbf{Z}), $^*\text{rational numbers}$ (\mathbf{Q}), $^*\text{real numbers}$ (\mathbf{R}), and $^*\text{complex numbers}$ (\mathbf{C}) (\rightarrow 355 Real Numbers; 74 Complex Numbers).

The extensions up to the rationals are carried out to attain a domain within which the operations of addition, subtraction, multiplication, and division, namely, the **four arithmetic operations** (or **rational operations**) can be performed indefinitely, with division by 0 the only exception. To develop the theory of natural numbers there are two well-known methods, one being G. Peano's system of axioms [4], which will be stated below, and the other being R. Dedekind's set-theoretic treatment [5]. The domain of rational numbers can be extended, taking continuity into consideration, to that of real numbers by several methods of which the best known are those of the Dedekind cut (1872) [8], which will be described below, and of G. Cantor's

fundamental sequences (1872) [9]. There is also a way based on infinite series, given by K. Weierstrass in his lectures (1859–1860). Though in the domain of real numbers (1) the four arithmetic operations can be performed indefinitely and (2) an order relation for magnitude is defined, the equation $x^2 + 1 = 0$ has no root. Introducing numbers expressible as $a + ib$ ($i = \sqrt{-1}$), it is possible to solve every equation of the second order. Such numbers, once called imaginary, have been used since the days of G. Cardano [6] in the 16th century. L. Euler also made good use of complex numbers as convenient tools in many calculations and obtained among other things his formula $\exp i\theta = \cos \theta + i \sin \theta$. Indeed, the notation $i = \sqrt{-1}$ was used for the first time by Euler (1777). Furthermore, C. F. Gauss, giving imaginary numbers the name *complex numbers*, showed that any algebraic equation with numerical coefficients always has roots in the domain of complex numbers. The discovery of the geometric representation of complex numbers by several mathematicians in the late 18th and early 19th centuries and their use in many applications have made complex numbers indispensable in mathematics.

Though there are extensions of complex numbers, such as [†]Hamilton's quaternions or [†]Cayley numbers, it is generally accepted that when we speak of a *number* we usually mean a complex number.

B. Natural Numbers

Peano, basing his system on a specific natural number, 1, and a function such that to each natural number x corresponds a natural number $x + 1$ (hereafter denoted by x' and called the **successor** of x), formulated the fundamental properties of the set \mathbf{N} of natural numbers in the following five axioms, called the **Peano postulates**: (1) $1 \in \mathbf{N}$; (2) if $x \in \mathbf{N}$, then $x' \in \mathbf{N}$; (3) if $x \in \mathbf{N}$, then $x' \neq 1$; (4) if $x' = y'$ ($x, y \in \mathbf{N}$), then $x = y$; and (5) if a set M satisfies the two conditions: $1 \in M$, and $x \in M$ implies $x' \in M$, then $\mathbf{N} \subset M$. Since these postulates determine \mathbf{N} uniquely up to isomorphism, they can be regarded as a definition of \mathbf{N} . Elements of \mathbf{N} are called **natural numbers**.

Owing to Peano's fifth postulate, regarding a certain property $P(n)$ for natural numbers n we can deduce that $P(n)$ is true for every n if we prove both of the following conditions: (i) $P(1)$ is true; and (ii) for any natural number k , if $P(k)$ is true, then $P(k + 1)$ is true. Such reasoning is called **mathematical induction** (or **complete induction**). Accordingly, Peano's fifth postulate is called the **axiom of mathematical induction**. **Double mathematical induction**, a

generalization of mathematical induction, is as follows: to show that the property $P(m, n)$ is true for every pair of natural numbers m and n , we have only to show that (iii) $P(m, 1)$ and $P(1, n)$ are true for every m and every n ; and (iv) for every pair of natural numbers k and l , if $P(k + 1, l)$ and $P(k, l + 1)$ are true, then $P(k + 1, l + 1)$ is true. This axiom can be formulated in several other ways and can be generalized further to n -tuple mathematical inductions ($n = 2, 3, 4, \dots$), generically called **multiple mathematical inductions**.

Assume for a set M that a mapping f from the [†]Cartesian product $\mathbf{N} \times M$ into M is given. Then a mapping φ from \mathbf{N} into M such that (v) $\varphi(1) = a$; and (vi) $\varphi(x') = f(x, \varphi(x))$ ($x \in \mathbf{N}$) exists and is unique. Defining φ by (v) and (vi) is called the **definition of φ by mathematical induction**.

In particular, given a natural number a , the mapping $\varphi: \mathbf{N} \rightarrow \mathbf{N}$ defined by (vii) $\varphi(1) = a'$; and (viii) $\varphi(x') = \varphi(x)'$ is called **addition by a** . We shall write $\varphi(b) = a + b$, whence $x' = x + 1$. Addition thus defined obeys the following laws: $a + b = b + a$ (**commutative law**); $(a + b) + c = a + (b + c)$ (**associative law**). Peano's postulates are thus equivalent to the following: (1') $1 \in \mathbf{N}$; (2') for each pair $a, b \in \mathbf{N}$, $a + b \in \mathbf{N}$ is defined so that addition obeys the commutative and associative laws; (3') for each pair of natural numbers a and b , one and only one of the following three relations holds: $a = b + c$ ($c \in \mathbf{N}$); $a = b$; $a + c = b$ ($c \in \mathbf{N}$); (4') the same as (5) (mathematical induction). From (1')–(4') follows the **cancellation law**: $a + c = b + c \Leftrightarrow a = b$. Define $a \geq b$ if and only if $a = b$ or $a = b + c$ ($a, b, c \in \mathbf{N}$). Then, from (3'), \mathbf{N} becomes a [†]totally ordered set and $a \geq b \Leftrightarrow a + c \geq b + c$.

For each $a \in \mathbf{N}$, the mapping $\varphi: \mathbf{N} \rightarrow \mathbf{N}$ defined by $\varphi(1) = a$ and $\varphi(x') = \varphi(x) + a$ is called **multiplication by a** , and we write $\varphi(b) = ab$ (or $a \cdot b$). Multiplication obeys the following laws: $ab = ba$ (**commutative law**); $(ab)c = a(bc)$ (**associative law**); $a(b + c) = ab + ac$, $(a + b)c = ac + bc$ (**distributive laws**); and $ac = bc \Leftrightarrow a = b$ (**cancellation law**). The statement $a \cdot 1 = 1 \cdot a = a$ also holds.

Natural numbers, which have been introduced thus far as [†]ordinal numbers, also have the properties of [†]cardinal numbers. Denoting $\{1, 2, \dots, n\} = M_n$, we have $\overline{M_n} = \overline{M_m} \Leftrightarrow m = n$, $\overline{M_m} + \overline{M_n} = \overline{M_{m+n}}$, $\overline{M_m} \times \overline{M_n} = \overline{M_{mn}}$ (\rightarrow 49 Cardinal Numbers).

C. Integers

Introducing new numbers which are not in $\mathbf{N} = \{1, 2, \dots\}$, represented by the notations $0, -1, -2, \dots, -n, \dots$, we write $\mathbf{Z} = \{\dots,$

$-n, \dots, -2, -1, 0, 1, 2, \dots, n, \dots\}$. An element of \mathbf{Z} is called an **integer** (or **rational integer**).

Algebraically we can construct \mathbf{Z} from \mathbf{N} as follows: Let the set of all \dagger ordered pairs (k, l) of natural numbers k, l be $M = \mathbf{N} \times \mathbf{N}$, and define in M an \dagger equivalence relation $(k, l) \sim (m, n)$ by $k + n = m + l$. Let the equivalence class of (k, l) be $K(k, l)$, and construct the \dagger quotient space, $M/\sim = M^*$. Then the mapping $\varphi: \mathbf{Z} \rightarrow M^*$ defined by $\varphi(n) = K(k + n, k)$, $\varphi(0) = K(k, k)$, $\varphi(-n) = K(k, k + n)$ is bijective. Setting $K(k, l) + K(m, n) = K(k + m, l + n)$, addition can be defined in M^* (and accordingly in \mathbf{Z}) which is an extension of that in \mathbf{N} . Since $K(k, l) - K(m, n) = K(k + n, l + m)$, subtraction can be defined in \mathbf{Z} . This makes \mathbf{Z} an \dagger Abelian group with respect to addition. An order relation in \mathbf{Z} is defined by $K(k, l) \geq K(m, n) \Leftrightarrow k + n \geq m + l$, which makes \mathbf{Z} a totally ordered set. This order relation is an extension of that in \mathbf{N} . In particular, $\mathbf{N} = \{a \in \mathbf{Z} | a > 0\}$. Furthermore, setting $K(k, l) \times K(m, n) = K(km + ln, kn + lm)$, multiplication in \mathbf{Z} can be defined. It is an extension of that in \mathbf{N} and obeys commutative, associative, and distributive laws. Also, for each $a, b \in \mathbf{Z}$, we have $ab = 0 \Leftrightarrow (a = 0 \text{ or } b = 0)$. Thus, \mathbf{Z} becomes an \dagger integral domain.

D. Rational Numbers

Let P be the set of all ordered pairs (a, b) of integers a, b with $b \neq 0$, and define in P an equivalence relation $(a, b) \sim (c, d)$ by $ad = bc$. Each equivalence class determined by this relation is called a **rational number**. Denoting by $L(a, b)$ the equivalence class to which (a, b) belongs, we can define the sum $x + y$, the difference $x - y$, the product xy , and the quotient x/y of rational numbers $x = L(a, b)$, $y = L(c, d)$, as in the cases of addition and multiplication of integers, in the following way: $x + y = L(ad + bc, bd)$, $x - y = L(ad - bc, bd)$, $xy = L(ac, bd)$, $x/y = L(ad, bc)$, where the quotient is defined only when $c \neq 0$. Thus the set \mathbf{Q} of all rational numbers becomes a \dagger field.

For the same reason that we have identified integers of a special type with natural numbers, we now identify a rational number expressible as $L(a, 1)$ with an integer a . Henceforth, any rational number $L(a, b)$ ($b \neq 0$) can be expressed in the form of a quotient a/b ($b \neq 0$) of integers a and b .

From $L(a, b) = L(ca, cb)$ ($c \neq 0$), it is always possible to assume $b > 0$ in the representation $L(a, b)$ of a rational number x . For any two rational numbers $x = L(a, b)$, $y = L(c, d)$ with $b > 0$, $d > 0$, define an ordering in \mathbf{Q} by $x \geq y \Leftrightarrow ad \geq bc$, which is an extension of the ordering of integers. Thus (i) \mathbf{Q} becomes totally

294 E Numbers

ordered, and we have (ii) $x \geq y \Rightarrow x + z \geq y + z$ and (iii) $x \geq y$ and $z \geq 0 \Rightarrow xz \geq yz$. The rational x is called **positive** if $x > 0$ and **negative** if $x < 0$.

E. Real Numbers

Two typical methods of constructing real numbers from rational numbers are those of Dedekind and of Cantor.

Dedekind's Theory of Real Numbers. We call a pair (A_1, A_2) of subsets A_1, A_2 of the set \mathbf{Q} of all rational numbers a **cut** of \mathbf{Q} if they satisfy the following conditions: (i) $A_1 \neq \emptyset$, $A_2 \neq \emptyset$; (ii) $\mathbf{Q} = A_1 \cup A_2$; (iii) $a_1 \in A_1, a_2 \in A_2 \Rightarrow a_1 < a_2$. Then the following three cases are distinguished: there is (i) a maximum in A_1 with no minimum in A_2 ; (ii) no maximum in A_1 with a minimum in A_2 ; or (iii) no maximum in A_1 with no minimum in A_2 . A cut with either condition (i) or (iii) is called a **real number** (in the sense of Dedekind); condition (ii) can be converted to (i). The set of all real numbers is denoted hereafter by \mathbf{R} and each real number by α or β or A real number with property (i) is called a **rational real number**, and a real number with property (iii) an **irrational real number**. Any rational real number is uniquely determined by the maximum a^* of A_1 , and the mapping: $a \rightarrow a^* = (A_1, A_2)$ from the set \mathbf{Q} of rational numbers onto the set \mathbf{Q}^* of rational real numbers is bijective.

I. For real numbers $\alpha = (A_1, A_2)$ and $\beta = (B_1, B_2)$ we define $\alpha \leq \beta$ if and only if $A_1 \subset B_1$. By this ordering \leq , \mathbf{R} becomes a totally ordered set.

II. For real numbers $\alpha = (A_1, A_2)$ and $\beta = (B_1, B_2)$, put $C_2 = \{a + b | a \in A_2, b \in B_2\}$ and $C_1 = \mathbf{R} - C_2$; then $(C_1, C_2) = \gamma$ is a real number. Define the sum $\alpha + \beta$ by setting $\alpha + \beta = \gamma$. Addition thus defined obeys commutative and associative laws, and \mathbf{R} becomes an \dagger Abelian group with 0^* as its zero element. Furthermore, for real numbers $\alpha = (A_1, A_2)$ and $\beta = (B_1, B_2)$ with $0^* \leq \alpha$, $0^* \leq \beta$, put $D_2 = \{ab | a \in A_2, b \in B_2\}$, $D_1 = \mathbf{R} - D_2$; then $(D_1, D_2) = \delta$ becomes a real number. Define the product $\alpha\beta$ by setting $\alpha\beta = \delta$. According as $0^* > \alpha$, $0^* \leq \beta$; $0^* \leq \alpha$, $0^* > \beta$; or $0^* > \alpha$, $0^* > \beta$, define $\alpha\beta = -((- \alpha)\beta)$; $\alpha\beta = -(\alpha(-\beta))$; and $\alpha\beta = (-\alpha)(-\beta)$, respectively. Multiplication thus defined obeys the commutative, associative, and distributive laws, and \mathbf{R} becomes a field with 1^* as its unity element.

III. For ordering and arithmetic operations, we have (1) $\alpha \geq \beta \Rightarrow \alpha + \gamma \geq \beta + \gamma$; and (2) $\alpha \geq \beta$, $\gamma \geq 0^* \Rightarrow \alpha\gamma \geq \beta\gamma$.

By letting each rational number a corre-

spond to a rationally real number a^* , we can set up a bijection between the set \mathbf{Q} of all rational numbers and \mathbf{Q}^* . Furthermore, in this correspondence, the sum, product, 0, and 1 of \mathbf{Q} are mapped to the sum, product, zero element, and unity element of \mathbf{Q}^* , respectively; in addition, the ordering is preserved. Thus \mathbf{Q} and \mathbf{Q}^* are isomorphic with respect to both arithmetic operations and ordering. We shall hereafter identify the element a^* with a . Accordingly we call rational real numbers simply **rational numbers** and similarly irrational real numbers simply **irrational numbers**.

IV. Similarly as for \mathbf{Q} , we can define a cut (A_1, A_2) of the set of all real numbers \mathbf{R} (precisely, by the conditions $A_1 \neq \emptyset$, $A_2 \neq \emptyset$; $\mathbf{R} = A_1 \cup A_2$; $d_1 \in A_1, d_2 \in A_2 \Rightarrow d_1 < d_2$). For each cut (A_1, A_2) of \mathbf{R} , either there is a maximum in A_1 and no minimum in A_2 or no maximum in A_1 and a minimum in A_2 (Dedekind). This property is called the **connectedness** (or **continuity**) of real numbers.

By using definitions (I)–(IV), any real number α can be represented (i) as the †least upper bound of some set A of rational numbers: $\alpha = \sup A$; and also (ii) as the limit of a sequence $\{a_n\}$ of rational numbers: $\alpha = \lim a_n$.

Cantor's Theory of Real Numbers. A sequence $\{a_n\}$ of rational numbers is called a **fundamental sequence** (or **Cauchy sequence**) if it satisfies the following condition: for each positive rational number ε , there exists a natural number n_0 such that $-\varepsilon < a_n - a_m < \varepsilon$ for every a_m and a_n with $m > n_0$ and $n > n_0$. For two Cauchy sequences $\{a_n\}$ and $\{b_n\}$, we can write $\{a_n\} \sim \{b_n\}$ if $\{a_1, b_1, a_2, b_2, \dots, a_n, b_n, \dots\}$ is again a Cauchy sequence. The relation \sim is an equivalence relation. Let \mathbf{R}' be the set of all equivalence classes obtained by classifying, with respect to \sim , the set of all Cauchy sequences, and call an element of \mathbf{R}' (an equivalence class) a **real number** (in the sense of Cantor). We shall write $[\{a_n\}]$ hereafter for the equivalence class of $\{a_n\}$. In particular, $\{a_n\}$ with $a_n = a$ ($n = 1, 2, \dots$) being a Cauchy sequence, we denote a real number $[\{a_n\}]$ by a^{**} . An element of \mathbf{R}' of this type is called a **rational real number** (in the sense of Cantor), while one not of this type is called an **irrational real number** (in the sense of Cantor).

For each pair of real numbers $\alpha = [\{a_n\}]$ and $\beta = [\{b_n\}]$, their sum and product are uniquely defined by $\alpha + \beta = [\{a_n + b_n\}]$ and $\alpha\beta = [\{a_nb_n\}]$, where both $\{a_n + b_n\}$ and $\{a_nb_n\}$ are shown to be Cauchy sequences. Further, for α and β , define $\alpha < \beta$ if $a_n < b_n$ hold for all n larger than some number n_0 . As regards arithmetic operations and ordering, \mathbf{R}' has the properties (I)–(IV) of Dedekind's theory. Further, any Cauchy sequence of which the terms

all are real numbers has a limit in \mathbf{R}' (**completeness of real numbers**).

The sets of real numbers obtained by the above two methods are isomorphic with respect to arithmetic operations and ordering (\rightarrow 355 Real Numbers).

F. Complex Numbers

To construct complex numbers from real ones, several methods have been devised, among which the one stated below is due to W. R. Hamilton.

An ordered pair (a, b) of real numbers a and b will be called a **complex number**. Arithmetic operations among complex numbers are defined as follows: $(a, b) + (c, d) = (a + c, b + d)$, $(a, b) - (c, d) = (a - c, b - d)$, $(a, b) \cdot (c, d) = (ac - bd, bc + ad)$, and

$$\frac{(a, b)}{(c, d)} = \left(\frac{ac + bd}{c^2 + d^2}, \frac{bc - ad}{c^2 + d^2} \right), \quad (c, d) \neq (0, 0).$$

According to these definitions, the set \mathbf{C} of all complex numbers becomes a †field with $(0, 0)$ and $(1, 0)$ as its †zero element and †unity element, respectively. $\mathbf{R}^* = \{(a, 0) | a \in \mathbf{R}\}$ is a †subfield of \mathbf{C} , and the mapping $\varphi: \mathbf{R} \rightarrow \mathbf{R}^*$ defined by $\varphi(a) = (a, 0)$ proves to be a field †isomorphism. Thus, identifying the element $(a, 0)$ of \mathbf{R}^* with the element a of \mathbf{R} , \mathbf{C} can be regarded as an †overfield of \mathbf{R} ($\mathbf{R} \subset \mathbf{C}$). Hence, the zero element of \mathbf{C} is the real number 0 and the unity element is the real number 1. The complex number $(0, 1)$ is called the **imaginary unit** and denoted by i . Thus we can write $a + bi$ as usual for a complex number (a, b) (\rightarrow 74 Complex Numbers).

295 (V.4) Number-Theoretic Functions

A. Recurrent Sequences

A (complex-valued) function that has the set of nonnegative integers (or the set \mathbb{N} of natural numbers) as its domain is called a **number-theoretic** (or **arithmetic**) **function**. Thus it can be regarded as a sequence of numbers. We first consider recurrent sequences. Let $f(x_0, x_1, \dots, x_{r-1})$ be a complex-valued function of r variables. Put $u_0 = a_0$, $u_1 = a_1, \dots, u_{r-1} = a_{r-1}$, and successively define $u_{i+r} = f(u_i, u_{i+1}, \dots, u_{i+r-1})$ ($i = 0, 1, 2, \dots$). The sequence $\{u_n\}$ thus defined is called a **recurrent sequence of order r** determined by the initial values a_0, a_1, \dots, a_{r-1} and the function f . In particular, when the defining function f is given by $\sum_{i=0}^{r-1} b_i x_i$, $\{u_n\}$ is called a **linear recurrent sequence**. The **Fibonacci sequence** is a special linear recurrent sequence with initial values a_0, a_1 and the defining function $x_0 + x_1$. Let $\alpha = (1 + \sqrt{5})/2$, $\beta = (1 - \sqrt{5})/2$ be two roots of $1 + x = x^2$, and let c_1 and c_2 be determined by $c_1 + c_2 = a_0$ and $c_1\alpha + c_2\beta = a_1$. Then the Fibonacci sequence with the initial values a_0, a_1 is given by putting $u_n = c_1\alpha^n + c_2\beta^n$ ($n = 0, 1, 2, \dots$). If we put $a_0 = 1$, $a_1 = 1$, then we obtain **Binet's formula**:

$$u_n = \frac{1}{\sqrt{5}} \left\{ \left(\frac{1 + \sqrt{5}}{2} \right)^{n+1} - \left(\frac{1 - \sqrt{5}}{2} \right)^{n+1} \right\}.$$

B. Multiplicative Functions

A number-theoretic function f with domain \mathbb{N} is said to be **multiplicative** if $f(1) = 1$, $f(mn) = f(m)f(n)$ for $(m, n) = 1$, and to be **completely multiplicative** if $f(1) = 1$, $f(mn) = f(m)f(n)$ for any m and n ($\in \mathbb{N}$). Similarly, f is said to be **additive** if $f(1) = 0$, $f(mn) = f(m) + f(n)$ for $(m, n) = 1$, and to be **completely additive** if $f(1) = 0$

and $f(mn) = f(m) + f(n)$ for any m and n ($\in \mathbb{N}$). If f is multiplicative and $\sum_{n=1}^{\infty} f(n)$ is absolutely convergent, then $\sum_{v=0}^{\infty} f(p^v)$ is absolutely convergent for any prime p . Moreover, we have

$$\sum_{n=1}^{\infty} f(n) = \prod_p \left(\sum_{v=0}^{\infty} f(p^v) \right),$$

where the infinite product on the right-hand side is also absolutely convergent. Furthermore, if $f(n)$ is completely multiplicative, then we have

$$\sum_{n=1}^{\infty} f(n) = \prod_p (1 - f(p))^{-1}.$$

In particular, for $f(n) = n^{-s}$, which is completely multiplicative (with $s = \sigma + it$ a complex variable), we get the \dagger Euler product formula for the \dagger Riemann zeta function:

$$\zeta(s) = \sum_{n=1}^{\infty} n^{-s} = \prod_p (1 - p^{-s})^{-1}$$

for $\sigma > 1$.

C. Convolutions

If f and g are number-theoretic functions, the **convolution $f * g$** is defined by

$$(f * g)(n) = \sum_{d|n} f(d)g(n/d),$$

with the summation carried over all divisors d of n . For any number-theoretic functions f, g, h , we have $f * g = g * f$ and $(f * g) * h = f * (g * h)$. If f and g are multiplicative number-theoretic functions, $f * g$ is again a multiplicative number-theoretic function.

The **Möbius function** $\mu(n)$ is defined as follows: $\mu(1) = 1$, $\mu(n) = 0$ if n is divisible by the square of a prime, and $\mu(n) = (-1)^r$ if n is the product of r distinct primes. It can easily be proved that μ is multiplicative and that

$$\sum_{d|n} \mu(d) = \begin{cases} 1 & (n = 1), \\ 0 & (n > 1). \end{cases}$$

Let e and ρ be functions defined by $e(1) = 1$, $e(n) = 0$ ($n > 1$), and $\rho(n) = 1$ for every n . Then e is the identity element for the convolution $*$, and $\mu * \rho = \rho * \mu = e$. It follows that $f * \rho = g$ is equivalent to $f = g * \mu$, that is,

$$g(n) = \sum_{d|n} f(d)$$

implies that

$$f(n) = \sum_{d|n} \mu(d)g(n/d),$$

and vice versa. We call the latter the **Möbius inversion formula**. Similarly, for complex-valued functions F, G defined on $[1, +\infty)$,

$$G(x) = \sum_{n \leq x} F(x/n)$$

Number-Theoretic Functions

is equivalent to

$$F(x) = \sum_{n \leq x} \mu(n) G(x/n).$$

Let $\varphi(n)$ be the number of integers m not greater than n and such that $(m, n) = 1$. The function $\varphi(n)$, called the **Euler function**, is multiplicative, and we have

$$\varphi(n) = n \prod_{p|n} \left(1 - \frac{1}{p}\right) = n \sum_{d|n} \frac{\mu(d)}{d},$$

and $\varphi(p^n) = p^n - p^{n-1}$ for every prime p . Let v be the function defined by $v(n) = n$ for every n . Then we have $\mu * v = \varphi$ and $v = \rho * \varphi$, and hence $\sum_{d|n} \varphi(d) = n$.

The **generalized divisor function** $d_k(n)$ is the number of ways of expressing n as a product of k factors. Thus we have

$$d_k(n) = \sum_{n_1 n_2 \dots n_k = n} 1 = \sum_{m|n} d_{k-1}(m),$$

and $d_k = \rho * \dots * \rho$ (k factors). Therefore, d_k is multiplicative. For simplicity, we write $d(n)$ instead of $d_2(n)$. Then $d(n)$ is the number of divisors of n , and we call it the **divisor function**. For example, $d(12) = 6$. We denote by $\sigma_\alpha(n)$ the sum of α th powers of divisors of n . If $n = \prod_{p|n} p^l$, then we have

$$\sigma_\alpha(n) = \sum_{d|n} d^\alpha = \prod_{p|n} \frac{p^{\alpha(l+1)} - 1}{p^\alpha - 1},$$

and σ_α is also multiplicative. We write $\sigma_1(n) = \sigma(n)$. A number n satisfying $\sigma(n) = 2n$ is said to be a † perfect number. Let $n = \prod_{p|n} p^{l_p}$. The functions $\omega(n) = \sum_{p|n} 1$ (the number of distinct prime factors of n) and $\Omega(n) = \sum_{p|n} l_p$ (the number of prime factors of n) are often used, the former being additive and the latter completely additive.

D. Residue Characters and Gaussian Sums

Let k be a positive integer and χ be a completely multiplicative function such that $\chi(n) = 0$ for $(n, k) > 1$ and $\chi(n_1) = \chi(n_2)$ for $n_1 \equiv n_2 \pmod{k}$. The function χ is called a **Dirichlet character** (or **residue character**) with modulus k (or modulo k). There exist $\varphi(k)$ distinct characters modulo k for a given k . The character satisfying $\chi(n) = 1$ for every n coprime to k is called the **principal character** modulo k , and we denote it by χ_0 . It is easily proved that

$$\sum_{n=0}^{k-1} \chi(n) = \begin{cases} \varphi(k) & (\chi = \chi_0), \\ 0 & (\chi \neq \chi_0), \end{cases}$$

$$\sum_{\chi} \chi(n) = \begin{cases} \varphi(k) & (n \equiv 1 \pmod{k}), \\ 0 & (n \not\equiv 1 \pmod{k}). \end{cases}$$

Suppose that $k = k_1 k_2 \dots k_r$ ($(k_i, k_j) = 1, i \neq j$). Then there exist r characters χ_i modulo k_i permitting the unique decomposition $\chi = \chi_1 \chi_2 \dots \chi_r$.

Let χ be a character modulo k and $\rho = \exp(2\pi i/k)$. The **Gaussian sum** modulo k is defined by

$$G(a, \chi) = \sum_{n \pmod{k}} \chi(n) \rho^{an},$$

where n runs over a complete system modulo m (\rightarrow 297 Number Theory, Elementary, G). Hence if $a \equiv b \pmod{k}$, then $G(a, \chi) = G(b, \chi)$. Suppose that $k = k_1 k_2 \dots k_r$ ($(k_i, k_j) = 1, i \neq j$) and $a_i \equiv a \pmod{k_i}$. Then we have

$$G(a, \chi) = \varepsilon G(a_1, \chi_1) G(a_2, \chi_2) \dots G(a_r, \chi_r),$$

$$\varepsilon = \chi_1(k/k_1) \chi_2(k/k_2) \dots \chi_r(k/k_r),$$

where $\chi = \chi_1 \chi_2 \dots \chi_r$ is the decomposition of χ mentioned above.

Let k_0 be a divisor of k . If $\chi(n) = 1$ whenever $(n, k) = 1$ and $n \equiv 1 \pmod{k_0}$, then we say that χ is defined mod k_0 . The least positive integer $f = f(\chi)$ modulo to which χ is defined is called the **conductor** of χ . If the conductor of χ is k itself, then χ is said to be a **primitive character** modulo k . When χ has the decomposition $\chi = \chi_1 \dots \chi_r$, the conductor of χ is also decomposed as $f(\chi) = f(\chi_1) f(\chi_2) \dots f(\chi_r)$. If D is a square-free integer, then the † discriminant d of the quadratic number field $\mathbf{Q}(\sqrt{D})$ (where \mathbf{Q} is the rational number field) is either D ($D \equiv 1 \pmod{4}$) or $4D$ ($D \equiv 2, 3 \pmod{4}$). The integers d so represented are called the **fundamental discriminants**. The † Kronecker symbol (d/n) (\rightarrow 347 Quadratic Fields) is defined only for such fundamental discriminants. Z. Suetuna and A. Z. Walfisz (1936) proved that if $\chi(n)$ is a real primitive character modulo k , then we necessarily have one of the following cases: (i) $k = p_1 p_2 \dots p_r$; (ii) $k = 4p_1 p_2 \dots p_r$; or (iii) $k = 8p_1 p_2 \dots p_r$ (with the p_i distinct odd primes). In case (i),

$$\chi(n) = \begin{cases} (k/n) & (k \equiv 1 \pmod{4}), \\ (-k/n) & (k \equiv -1 \pmod{4}); \end{cases}$$

in case (ii),

$$\chi(n) = \begin{cases} (-k/n) & (k/4 \equiv 1 \pmod{4}), \\ (k/n) & (k/4 \equiv -1 \pmod{4}); \end{cases}$$

and in case (iii), $\chi(n)$ is either (k/n) or $(-k/n)$.

If χ is a primitive character modulo k , then $G(a, \chi) = \bar{\chi}(a) G(1, \chi)$, $G(1, \chi) \bar{G}(1, \chi) = k$. In particular, if χ is a real primitive character, then

$$G(1, \chi) = \begin{cases} \sqrt{k} & (\chi(-1) = 1), \\ i\sqrt{k} & (\chi(-1) = -1). \end{cases}$$

Sometimes $S(a, k) = \sum_{n \pmod{k}} \rho^{an^2}$ is called the Gaussian sum, where $\rho = \exp(2\pi i/k)$. If $(a, k_i) = 1$ ($i = 1, 2$) and $(k_1, k_2) = 1$, then $S(a, k_1 k_2) = S(ak_2, k_1) S(ak_1, k_2)$. If $(a, 2) = 1$, then

$$S(a, 2^r) = \begin{cases} 0 & (r = 1), \\ (1 + i^a) 2^{r/2} & (r \text{ even}), \\ 2^{\pi i a/4} \cdot 2^{(r+1)/2} & (r \text{ odd } > 1). \end{cases}$$

Let p be an odd prime and $(a, p) = 1$. Then we have

$$S(a, p^r) = \begin{cases} (a/p)S(1, p) & (r=1), \\ p^{r/2} & (r \text{ even}), \\ p^{(r-1)/2}S(a, p) & (r \text{ odd} > 1), \end{cases}$$

where (a/p) is the \dagger Legendre symbol (\rightarrow 297 Number Theory, Elementary, H). The well-known **Gauss formula** is stated as follows:

$$S(1, p) = \begin{cases} \sqrt{p} & (p \equiv 1 \pmod{4}), \\ i\sqrt{p} & (p \equiv 3 \pmod{4}). \end{cases}$$

Various proofs of this formula have been given by many authors [5].

Let

$$G(a, \chi_0) = \sum'_{h \pmod{k}} \exp(2\pi i ah/k),$$

called the **Ramanujan sum**, be denoted by $c_k(a)$. The sum $\sum'_{h \pmod{k}}$ means that h runs through a reduced residue system modulo m (\rightarrow 297 Number Theory, Elementary, G). It follows that $c_k(1) = \mu(k)$ and

$$c_k(a) = \sum_{d|(k,a)} \mu\left(\frac{k}{d}\right)d.$$

E. Analytic Methods

Let f be a number-theoretic function. One of the problems in analytic number theory is to estimate $\sum_{n \leq x} f(n)$ or to expand it into series. We assume that $f(x)$ and $g(x)$ are real-valued functions defined for $x \geq 1$ and $g(x)$ is of class C^1 . Then we have

$$\sum_{n \leq x} f(n)g(n) = F(x)g(x) - \int_1^x F(t)g'(t)dt,$$

where $F(x) = \sum_{n \leq x} f(n)$. If we take $f(x) = 1$, $g(x) = \log x$ or $1/x$ in this formula, then we obtain

$$\sum_{n \leq x} \log n = x \log x - x + O(\log x)$$

or

$$\sum_{n \leq x} n^{-1} = \log x + C + O(x^{-1})$$

(where C is the \dagger Euler constant), respectively.

We now construct from the function f the Dirichlet series

$$F(s) = \sum_{n=1}^{\infty} f(n)n^{-s}$$

or the power series

$$P(x) = \sum_{n=1}^{\infty} f(n)x^n.$$

There are called the **generating functions** of f . The consideration of these functions makes possible the application of function-theoretic

methods to the problem in this section. Sometimes more complicated functions are used.

We mainly consider the generating function represented by the Dirichlet series. The generating functions of ρ , μ , d , χ (\rightarrow Sections C, D) are $\zeta(s) = \sum_{n=1}^{\infty} n^{-s}$, $\sum_{n=1}^{\infty} \mu(n)n^{-s}$, $\sum_{n=1}^{\infty} d(n)n^{-s}$, $L(s, \chi) = \sum_{n=1}^{\infty} \chi(n)n^{-s}$, respectively. The \dagger abscissa of absolute convergence of each of these Dirichlet series is 1. The function $L(s, \chi)$ is called the \dagger Dirichlet L -function (\rightarrow 123 Distribution of Prime Numbers; 450 Zeta Functions). When $k=1$ and $\chi = \chi_0$, $L(s, \chi)$ is precisely $\zeta(s)$.

Let $F(s)$, $G(s)$, and $H(s)$ be the generating functions of f , g , and $h = f * g$. Let f and g be multiplicative, so that h is also multiplicative. Moreover, if $F(s)$ and $G(s)$ are absolutely convergent for $\sigma \geq \sigma_0$, then $H(s)$ is also absolutely convergent for $\sigma \geq \sigma_0$, and $F(s)G(s) = H(s)$ for $\sigma \geq \sigma_0$. It follows from this that $\sum_{n=1}^{\infty} \mu(n)n^{-s} = \zeta^{-1}(s)$, $\sum_{n=1}^{\infty} \mu(n)\chi(n)n^{-s} = L(s, \chi)^{-1}$, $\sum_{n=1}^{\infty} d_k(n)n^{-s} = \zeta(s)^k$, and $\sum_{n=1}^{\infty} d^2(n)n^{-s} = \zeta^4(s)/\zeta(2s)$. The last result was given by S. Ramanujan. More generally, $\sum_{n=1}^{\infty} d^r(n)n^{-s} = \zeta^{2r}(s)\varphi(s)$, where $\varphi(s)$ is an analytic function for $\sigma > 1/2$. By utilizing analytic methods, we can deduce from this that $\sum_{n \leq x} d^r(n) \sim x(c_1(\log x)^{2^r-1} + \dots + c_{2^r})$ (B. M. Wilson, 1923) (\rightarrow 123 Distribution of Prime Numbers; 242 Lattice-Point Problems).

There are many formulas known as the **Euler summation formula**. Among them the following one is convenient to use (E. Landau, L. J. Mordell, H. Davenport): Let $f_0(x) = x - [x] - 1/2$ (when x is not an integer), $= 0$ (when x is an integer). We successively construct continuous functions $f_1(x)$, $f_2(x)$, ... of period 1 such that $f'_r(x) = f_{r-1}(x)$ ($r \geq 1$) if x is not an integer, and $\int_0^1 f_r(x)dx = 0$. If $F(x)$ is of class C^h on $[a, b]$, then using these auxiliary functions, we have

$$\begin{aligned} \sum'_{a \leq m \leq b} F(m) &= \int_a^b F(x)dx \\ &+ \sum_{r=0}^{h-1} (-1)^r (f_r(a)F^{(r)}(a) \\ &\quad - f_r(b)F^{(r)}(b)) \\ &+ (-1)^{h-1} \int_a^b f_{h-1}(x)F^{(h)}(x)dx, \end{aligned}$$

where \sum' means that the term corresponding to $m=a$ or $m=b$ in the sum is to be replaced by $F(a)/2$ or $F(b)/2$ whenever a or b is an integer. Since the \dagger Fourier series of $f_0(x)$ is

$$-\sum_{n=1}^{\infty} \frac{\sin(2\pi nx)}{n\pi}$$

(which is convergent), $f_r(x)$ can be expressed by

$$-\sum_{n=-\infty}^{\infty} \frac{\exp(2\pi inx)}{(2\pi in)^{r+1}},$$

where Σ' means that the term with $n=0$ is omitted and this sum actually means

$$\sum_{n=1}^{\infty} \left(\frac{\exp(2\pi i n x)}{(2\pi i n)^{r+1}} + \frac{\exp(-2\pi i n x)}{(-2\pi i n)^{r+1}} \right).$$

Hence if $h=1$, we have

$$\sum_{a \leq n \leq b} F(n) = \int_a^b F(x) dx - \frac{1}{\pi} \sum_{n=1}^{\infty} \frac{1}{n} \int_a^b F'(x) \sin(2\pi n x) dx.$$

For instance, if we put $h=1$, $a=1$, $b=N$, $F(x)=x^{-s}$ and let N tend to ∞ , then we have the formula

$$\zeta(s) = \sum_{n=1}^{\infty} n^{-s} = \frac{1}{s-1} + \frac{1}{2} - s \int_1^{\infty} \frac{f_0(x)}{x^{s+1}} dx \quad \text{for } \sigma > 1.$$

Utilizing the following integration by parts, the integral on the right-hand side can be extended so as to become holomorphic in s in the whole complex plane:

$$\int_1^{\infty} \frac{f_0(x)}{x^{s+1}} dx = -f_1(1) + (s+1) \int_1^{\infty} \frac{f_1(x)}{x^{s+2}} dx = \dots$$

Probabilistic considerations are also used for the study of various number-theoretic functions. If $f(n)$ is $\omega(n)$ or $\Omega(n)$, then we have $\sum_{n \leq x} f(n) = x \log \log x + cx + o(x)$. Therefore the average order of $\omega(n)$ or $\Omega(n)$ is estimated as $\log \log n$. Let $A(x; \alpha, \beta)$ be the number of n satisfying $n \leq x$ and $\log \log n + \alpha \sqrt{\log \log n} < f(n) < \log \log n + \beta \sqrt{\log \log n}$. Then

$$\lim_{x \rightarrow \infty} \frac{A(x; \alpha, \beta)}{x} = \frac{1}{\sqrt{2\pi}} \int_{\alpha}^{\beta} e^{-u^2/2} du.$$

For $f(n)=\omega(n)$, the result was proved by P. Erdős and M. Kac (1940) by using the †central limit theorem and V. Brun's †sieve method. Further general formulas were obtained by M. Tanaka (1955). Further development and the present state of probabilistic number theory can be seen in [7, 8].

Finally, we mention the well-known estimation formulas. Let ε be an arbitrary positive number and n be a positive integer. Then $d(n) = O(n^{\varepsilon})$, where O (†Landau's symbol) depends on ε . We know that $\limsup_{n \rightarrow \infty} (\log d(n)) \cdot (\log \log n) / \log n = \log 2$ (S. Wigert, 1907), and $\liminf_{n \rightarrow \infty} \omega(n) \cdot (\log \log n) / n = e^{-c}$. The result $\omega(n) = O(\log n / \log \log n)$ is often used. Let χ be a primitive character modulo k , and let $S_m = \sum_{n=1}^m \chi(n)$. We can prove that $|S_m| < \sqrt{k} \log k$ for all m (I. Schur, 1918) and $S_m = \Omega(\sqrt{k} \log \log k)$ (R. Paley, 1932). This formula, with the symbol

Ω , means that there exist infinitely many k satisfying $|S_m| > c\sqrt{k} \log \log k$ by taking m and χ suitably, with c any positive constant. Let χ be a character modulo k , and χ^0 be a primitive character associated with χ . Then we have $L(s, \chi) = L(s, \chi^0) \prod_{p|k} (1 - \chi^0(p)p^{-s})$. It follows that

$$\sum_{m=1}^n \chi(m) = \sum_{d: d|k, d|f} \mu(d) \chi^0(d) \sum_{m \leq n/d} \chi^0(m)$$

if the conductor of χ^0 is f . A. G. Postnikov investigated (1956) the sum of characters. The least integer that is not a quadratic residue modulo p does not exceed $p^{1/2} \sqrt{e} (\log p)^2$, where p is a sufficiently large prime (I. M. Vinogradov, 1926). The least integer that is a †primitive root modulo p does not exceed $2^{m+1} \sqrt{p}$, where m is the number of distinct prime divisors of $p-1$, with p a prime (L. K. Hua, 1942). D. A. Burgess (1962) deals with the latter results. We conclude with Artin's conjecture: If w is a given square-free integer, then there exist infinitely many primes p such that w is a primitive root modulo p . In 1967, C. Hooley proved this conjecture subject to the assumption that the general †Riemann hypothesis holds for †Dedekind zeta functions over certain †Kummer extensions of \mathbb{Q} . He also obtained the asymptotic formula for the number of such primes not exceeding x . Recently the †sieve method has been widely applied to the various investigations in the theory of number theoretic functions (\rightarrow 123 Distribution of Prime Numbers E).

296 (V.1) Number Theory

A. History

Simple and curious relations among integers were discovered and admired from antiquity. For example, we have the relation $3^2 + 4^2 = 5^2$, which has geometric meaning concerning right triangles. The Pythagoreans (\rightarrow 187 Greek Mathematics) sought similar relations. They were also interested in \dagger perfect numbers (numbers equal to the sum of their divisors, such as $28 = 1 + 2 + 4 + 7 + 14$). Modern arithmetic inherits from the Greeks the proof of the existence of an infinite number of primes, the \dagger Euclidean algorithm to obtain the greatest common divisor of two integers (both given in Euclid's *Elements*), and Eratosthenes' \dagger sieve for finding primes. In the 3rd century A.D., Diophantus of Alexandria discovered a method of solving indeterminate equations of degrees 1 and 2; this marked the origin of **Diophantine analysis**. The ancient Chinese also knew how to solve equations of the first degree in some special cases. Arithmetic also developed in India from an early period; its relation to Greek mathematics is not yet entirely clear. In the 12th century, the Indian mathematician Bhāskara knew how to solve \dagger Pell equations using a method much like Lagrange's.

Interest in integers was reborn in Europe in the 17th century. During this period, Bachet de Méziriac (1581–1638) rediscovered the solution of the \dagger Diophantine equation of the first degree and published it in his famous book on mathematical recreations [1]. Primes of the form $2^p - 1$, closely related to perfect numbers and called \dagger Mersenne numbers, attracted considerable interest. \dagger Fermat, sometimes called the father of number theory, announced numerous results without giving proofs; the most famous among them is the so-called Fermat's last theorem (\rightarrow 145 Fermat's Problem). Another famous conjecture of his is that every integer is expressible as the sum of at most n **n -gonal numbers**, i.e., numbers of the form $k(k-1)n/2 - k(k-2)$, $k \in \mathbb{N}$. This was proved by Gauss (for the case $n=3$), Jacobi ($n=4$), and Cauchy (for the general case).

In the 18th century, remarkable progress was made by Euler and Lagrange. The second part of Euler's *Algebra* [2] contains rich results of miscellaneous sorts in the field. Lagrange developed the theory of \dagger continued fractions and applied it to arithmetic. Toward the end of the 18th century, Legendre compiled his comprehensive book [3], from whose title originates the term *number theory*.

Gauss's *Disquisitiones* [4] appeared at about the same time as Legendre's book. The theoretical arithmetic of today originates from this work of Gauss. The book includes the theories of \dagger quadratic residues, \dagger quadratic forms, and **cyclotomy** (i.e., arithmetic theory of the roots of unity in the field of complex numbers), all of which appeared as well-developed theories of a remarkably high standard. The work was received with more respect than comprehension. Dirichlet made a lifelong effort to popularize the *Disquisitiones*; he also applied analytical methods to compute the \dagger class number of quadratic forms, thus giving number theory a new direction, the analytic theory of numbers. Gauss treated only binary quadratic forms; Eisenstein, Minkowski, and Siegel generalized the theory to the case of n variables. The algebraic theory of numbers has its origin in Gauss's paper on biquadratic residues. (\rightarrow 14 Algebraic Number Fields; 59 Class Field Theory; 118 Diophantine Equations; 182 Geometry of Numbers; 297 Number Theory, Elementary; 347 Quadratic Fields; 430 Transcendental Numbers.)

B. Analytic Methods

Analytic methods are sometimes used to solve arithmetic problems. For example, Legendre conjectured that any arithmetic progression of integers $a, a+d, a+2d, \dots$ contains an infinite number of primes if a and d are relatively prime. The conjecture was first proved by Dirichlet in 1837; in the proof he used an $\dagger L$ -function. Recently, proofs that do not use L -functions have been obtained, although these proofs are still not purely arithmetical. Analysis is indispensable in the formulation of some arithmetic problems. For example, let $x \in \mathbb{R}$ and $\pi(x)$ be the number of primes not exceeding x . Euclid's *Elements* already give the result $\pi(x) \rightarrow \infty$ as $x \rightarrow \infty$, but to describe the behavior of $\pi(x)$ as $x \rightarrow \infty$, notions of analysis are needed. Gauss conjectured that

$$\lim_{x \rightarrow \infty} \frac{\pi(x)}{x/\log x} = 1.$$

This \dagger prime number theorem was first proved in 1896, using the results of the theory of functions of a complex variable; more elementary proofs have been obtained in recent years.

Analysis is sometimes needed to solve or simplify certain problems in number theory. The branch of mathematics treating such problems is called **analytic number theory**. The question of the extent to which analysis is really needed in dealing with such problems is itself an interesting one.

In the 20th century, analytic number theory has made rapid progress. The problem of distribution of primes has been generalized to the case of algebraic number fields. †Additive number theory dealing with †Waring's problem, †Goldbach's problem, and other problems has developed and formed a new field. We also have **geometric number theory**, which deals with †lattice-point problems. (→ 4 Additive Number Theory; 123 Distribution of Prime Numbers; 242 Lattice-Point Problems; 295 Number-Theoretic Functions; 328 Partitions of Numbers; 450 Zeta Functions.)

297 (V.2) Number Theory, Elementary

A. The Euclidean Algorithm

We denote the set of natural numbers 1, 2, 3, ... by \mathbf{N} and the set of rational integers $0, \pm 1, \pm 2, \dots$ by \mathbf{Z} . Evidently \mathbf{Z} is an ordered †commutative ring and also an †integral domain with respect to ordinary addition and multiplication. For any $a \in \mathbf{Z}$ and $b \in \mathbf{N}$, there exists a unique pair of integers q and r such that $a = qb + r$ ($0 \leq r < b$) (**division algorithm**); q is called the **quotient** and r the **remainder** of the division of a by b . When the remainder r is zero, we say that a is a **multiple** of b , b is a **divisor** of a , and a is **divisible** by b . We denote this relation by $b|a$. After a finite number of divisions $a = q_1 b + r_1$, $b = q_2 r_1 + r_2$, $r_1 = q_3 r_2 + r_3$, ... ($b > r_1 > r_2 > \dots > 0$), we reach an equa-

tion of the form $r_k = q_{k+2} r_{k+1}$. The remainder $r = r_{k+1}$, uniquely determined in this manner by a and b , is the **greatest common divisor** (**G. C. D.**) of a and b . It can be expressed as $r = ax + by$ with integers x and y . This method of obtaining the G. C. D. is called the **Euclidean algorithm**. The greatest common divisor of a and b is denoted by (a, b) . If an integer c divides both a and b , then $c|(a, b)$. When $(a, b) = 1$, we say that a and b are **relatively prime**, and there are integral solutions x, y of the equation $ax + by = 1$. Given a pair of positive integers a and b , there exists a unique positive integer c that divides any common multiple of a and b , called the **least common multiple** (**L. C. M.**) of a and b . If d and l denote the G. C. D. and L. C. M. of a and b , respectively, we have $ab = dl$.

B. Prime Numbers

An integer p is called a **prime number** if p is larger than 1 and has no positive divisors other than 1 and itself. A positive integer is called a **composite number** if it has positive divisors other than 1 and itself. The following method of selecting the prime numbers from the sequence 2, 3, 4, 5, ..., known to the Greeks, is called **Eratosthenes' sieve**: First we discard multiples of two, thus reaching the second prime number, 3. Then we discard multiples of three and reach the next prime, 5. Continuing this process, we find the sequence of primes 2, 3, 5, 7, 11, ... by sifting out all multiples.

C. Decomposition into Primes Factors

Every integer $n > 1$ can be uniquely expressed as the product of primes; the resulting decomposition can be written as $n = p^\alpha q^\beta r^\gamma \dots$ with distinct prime factors p, q, r, \dots and corresponding exponents $\alpha, \beta, \gamma, \dots$ uniquely determined by n . This theorem is called the **fundamental theorem of elementary number theory**.

D. Perfect Numbers

We denote by $\sigma(n)$ the sum of positive divisors of n (including 1 and n itself). According as $\sigma(n)$ is greater than, equal to, or less than $2n$, we call n an **abundant number**, **perfect number**, or **deficient number**. An even number is perfect if and only if it can be represented as $n = 2^{e-1} \cdot (2^e - 1)$ with prime $2^e - 1$ (L. Euler). The existence of an odd perfect number still constitutes an open question. It is well known that, if n is odd and perfect, then n must be of the

form $n = p_0^{a_0} p_1^{a_1} \dots p_t^{a_t}$, where $p_0 \equiv a_0 \equiv 1 \pmod{4}$, and a_i is even for $i > 0$. Recently it has been proved that t must be ≥ 7 (P. H. Hagsis, Jr., *Math. Comp.*, 35 (1980)). Many necessary conditions for an odd number to be perfect have been given and repeatedly improved. It has been recently proved that there exists no odd perfect number less than 10^{50} (Hagsis, *Math. Comp.*, 27 (1973)).

Two numbers m and n are said to form a pair of **amicable numbers** if $\sigma(n) - n = m$ and $\sigma(m) - m = n$ (e.g., $m = 220$ and $n = 284$). Euler listed 61 such pairs. The following two numbers m, n , both having 152 digits, constitute the largest amicable pair currently known:

$$m = 3^4 \cdot 5 \cdot 11 \cdot 5281^{19} \cdot 29 \cdot 89 (2 \cdot 1291 \cdot 5281^{19} - 1),$$

$$n = 3^4 \cdot 5 \cdot 11 \cdot 5281^{19} (2^3 \cdot 3^3 \cdot 5^2 \cdot 1291 \cdot 5281^{19} - 1)$$

(H. J. J. te Riele, *Math. Comp.*, 28 (1974)).

E. Lionnet considered the numbers n such that the product $\prod_{d|n} d$ is equal to n^2 and called such numbers **perfect numbers of the second kind**, e.g., $n = p^3$, $n = pp'$, where p and p' are unequal prime numbers. It is also known that there are numbers n such that $\sigma(n)/n$ is an integer. For example, $2^5 \cdot 3 \cdot 7$, $2^{15} \cdot 3^5 \cdot 5^2 \cdot 7^2 \cdot 11 \cdot 13 \cdot 17 \cdot 19 \cdot 31 \cdot 43 \cdot 257$ have this property.

E. Mersenne Numbers

A number of the form $2^e - 1$, where e is a prime, is called a **Mersenne number**. For the number $2^e - 1$ to be prime, it is necessary but not sufficient that e be prime. If a Mersenne number is a prime, it is called a **Mersenne prime**. It is not known whether there are infinitely many Mersenne primes; it has been verified, however, that for $e < 44500$, there are 27 cases of e such that $2^e - 1$ is a Mersenne prime; $e = 2, 3, 5, 7, 13, 17, 19, 31, 61, 89, 107, 127, 521, 607, 1279, 2203, 2281, 3217, 4253, 4423, 9689, 9941, 11213, 21701, 23209$, and 44497. Until the 18th century, the verifications for $e \leq 31$ were done by direct calculation. For $61 \leq e \leq 127$, the "Lucas test" was utilized to execute the computation. The remaining cases were calculated by means of electronic computers. The number $2^{44497} - 1$, which has 13395 digits, is at present the largest known prime.

F. Fermat Numbers

Numbers of the form $2^{2^v} + 1$ are called **Fermat numbers**. For a number $p = 2^e + 1$ to be a prime, it is necessary that e be a power of 2.

Fermat conjectured that numbers of the form $2^{2^v} + 1$ are all primes. In fact, for $v = 0, 1, 2, 3, 4$, the corresponding $p = 3, 5, 17, 257, 65537$ are primes; however, $2^{2^5} + 1$ is divisible by 641. It is not yet known whether there exist Fermat primes other than these five primes. For further details \rightarrow [10]. Fermat numbers are closely connected with the problem of \dagger geometric construction of regular polygons.

G. Congruence

Let m be a positive integer. Two integers a and b are said to be **congruent modulo m** if their difference is divisible by m ; we denote this relation by the **congruence** $a \equiv b \pmod{m}$ (or simply by $a \equiv b \pmod{m}$) and call m the **modulus** of this congruence. Congruence modulo m is an \dagger equivalence relation, which is compatible with the ring operations and classifies \mathbb{Z} into m classes. We thus obtain the \dagger residue class ring $\mathbb{Z}/m\mathbb{Z}$ with m elements. If p is a prime, then $\mathbb{Z}/p\mathbb{Z}$ is a field which is isomorphic to the \dagger prime field with \dagger characteristic p . A complete system of representatives of the quotient set $\mathbb{Z}/m\mathbb{Z}$ is called a **complete residue system modulo m** . On the other hand, a set of $\varphi(m)$ elements n_i (φ is \dagger Euler's function) such that $n_i \not\equiv n_j \pmod{m}$ ($i \neq j$) and $(n_i, m) = 1$ is called a **reduced residue system modulo m** . The set of all residue classes represented by a reduced residue system modulo m forms a multiplicative Abelian group of order $\varphi(m)$; we denote this group by $(\mathbb{Z}/m\mathbb{Z})^*$. If $(a, m) = 1$, then $a^{\varphi(m)} \equiv 1 \pmod{m}$. If p is a prime and $(a, p) = 1$, then $a^{p-1} \equiv 1 \pmod{p}$ (**Fermat's theorem**), since $\varphi(p) = p - 1$. When m is 2, 4, p^k or $2p^k$ ($p \neq 2$; $k = 1, 2, \dots$), $(\mathbb{Z}/m\mathbb{Z})^*$ is a \dagger cyclic group, whose \dagger generator g is called a **primitive root modulo m** (\rightarrow Appendix B, Table 1). For any a prime to m and generator g of $(\mathbb{Z}/m\mathbb{Z})^*$, there exists a unique number μ ($1 \leq \mu \leq \varphi(m)$) such that $a \equiv g^\mu \pmod{m}$. We call μ the **index** of a with respect to the basis g , and write $\mu = \text{Ind}_g a$ (\rightarrow Appendix B, Table 2). The group $(\mathbb{Z}/2^k\mathbb{Z})^*$ ($k \geq 3$) is Abelian of type $(2, 2^{k-2})$, a basis of which is formed by the residue classes represented by -1 and 5. From this follows $(p-1)! \equiv -1 \pmod{p}$ (**Wilson's theorem**). Generally, if $m = \prod_{i=1}^r m_i$, $(m_i, m_j) = 1$ for $i \neq j$, then we have $\mathbb{Z}/m\mathbb{Z} \cong \mathbb{Z}/m_1\mathbb{Z} + \dots + \mathbb{Z}/m_r\mathbb{Z}$ (direct sum) and $(\mathbb{Z}/m\mathbb{Z})^* \cong (\mathbb{Z}/m_1\mathbb{Z})^* \times \dots \times (\mathbb{Z}/m_r\mathbb{Z})^*$ (direct product).

The congruence $ax \equiv b \pmod{m}$ with $(a, m) = d$ is solvable if and only if $d|b$, and when it is solvable, the solution is unique modulo m/d . The simultaneous congruences $x \equiv a_i \pmod{m_i}$ ($i = 1, 2, \dots, k$) are solvable if and only if $a_i \equiv a_j \pmod{(m_i, m_j)}$ ($i, j = 1, \dots, k$), and when they are solvable, the solution is unique modulo the

greatest common multiple of m_1, \dots, m_k . In particular, when $(m_i, m_j) = 1$ ($i \neq j$), the solution is unique modulo $m_1 m_2 \dots m_k$ (**Chinese remainder theorem**). If $m = p_1^{e_1} \dots p_k^{e_k}$ is the factorization of m , solving the congruence $f(x) \equiv 0 \pmod{m}$, where $f(x)$ is a polynomial with integral coefficients, can be reduced to solving $f(x) \equiv 0 \pmod{p_i^{e_i}}$ ($i = 1, \dots, k$). Also, solving a quadratic congruence can be reduced to solving a linear congruence and a congruence of the form $x^2 \equiv a \pmod{m}$.

H. Quadratic Residues

When the congruence $x^2 \equiv a \pmod{m}$, where $(a, m) = 1$, is solvable, a is said to be a **quadratic residue** modulo m ; otherwise, a is said to be a **quadratic nonresidue** modulo m . The following two conditions are necessary and sufficient for a to be a quadratic residue modulo m : (i) a is a quadratic residue with respect to each of the prime factors p ($p \neq 2$); and (ii) $a \equiv 1 \pmod{4}$ or $a \equiv 1 \pmod{8}$ according as $4|m$ or $8|m$.

Given a prime number p and integer a prime to p , the **Legendre symbol** (a/p) is by definition 1 or -1 according as a is a quadratic residue modulo p or not. The value of this symbol is determined by $a \pmod{p}$, and we have $(ab/p) = (a/p)(b/p)$. Hence the symbol determines a \dagger character of $(\mathbf{Z}/p\mathbf{Z})^*$ of order 2. Furthermore, the congruence $(a/p) \equiv a^{(p-1)/2} \pmod{p}$ holds (**Euler's criterion**).

I. Reciprocity Law

For odd primes p and q ($p \neq q$), the formulas

$$(p/q)(q/p) = (-1)^{((p-1)/2)((q-1)/2)}, \\ (-1/p) = (-1)^{(p-1)/2}, \quad (2/p) = (-1)^{(p^2-1)/8}$$

are called the **law of quadratic reciprocity of the Legendre symbol**, the **first complementary law**, and the **second complementary law**, respectively. These laws were conjectured by Euler and first proved by Gauss, who gave seven different proofs. We now have more than fifty different proofs of these laws. P. Bachmann (*Niedere Zahlentheorie I* (1902)) lists the 47 different proofs of the laws known at the time. Gauss's first proof was elementary; his second proof used quadratic forms. The latter has been reformulated utilizing the theory of quadratic fields [4]. The fourth proof used \dagger Gaussian sums, and the sixth proof used algebraic congruences with integral coefficients. His seventh proof, contained in his posthumous works, used congruences of higher degree [4]. His fourth, sixth, and seventh proofs are related to the arithmetic of \dagger cyclo-

tomic fields [4]. The third and fifth proofs are the most elementary and simple. They are based on Gauss's lemma: Let $r_1, r_2, \dots, r_{(p-1)/2}$ be the residues of divisions of $1a, 2a, \dots, (p-1)a/2$ by an odd prime p , and let n be the number of these residues that are greater than $p/2$. Then we have $(a/p) = (-1)^n$. T. Takagi gave a simplified exposition of the third proof using geometric figures (1904). The same method was rediscovered by G. Frobenius (1914).

When m is an odd integer such that $m = \pm \prod_i p_i^{e_i}$, $(m, n) = 1$, we call $(n/m) = \prod_i (n/p_i)^{e_i}$ **Jacobi's symbol**. If m has no square factor, it is a character of $(\mathbf{Z}/m\mathbf{Z})^*$. If we put $\text{sgn } m = +1$ or -1 according as $m > 0$ or $m < 0$, we have the following **law of quadratic reciprocity of Jacobi's symbol** and its **complementary laws**:

If m and n are relatively prime odd numbers, then

$$(m/n)(n/m) \\ = (-1)^{((m-1)/2)((n-1)/2) + ((\text{sgn } m-1)/2)((\text{sgn } n-1)/2)}, \\ (-1/n) = (-1)^{(n-1)/2 + (\text{sgn } n-1)/2}, \\ (2/n) = (-1)^{(n^2-1)/4},$$

where

$$n^* = (-1)^{(n-1)/2} n.$$

Furthermore, \dagger Kronecker's symbol, another generalization of the Legendre symbol, is used in the theory of quadratic number fields (\rightarrow 347 Quadratic Fields).

298 (XV.6) Numerical Computation of Eigenvalues

A. General Remarks

Numerical computation of †eigenvalues and †eigenvectors of a matrix provides a basic technique for the numerical solution of various eigenvalue problems. Roughly speaking, there are two kinds of method. In methods of the first kind, one determines the †characteristic polynomial $p(\lambda) = \det(\lambda I - A)$ (where I is the unit matrix) of A (or to give an algorithm to calculate the value of $p(\lambda)$ for an arbitrary λ), then solves the algebraic equation $p(\lambda) = 0$ numerically to obtain the eigenvalues λ_μ ($\mu = 1, 2, \dots$) (\rightarrow 301 Numerical Solution of Algebraic Equations), and finally to one determines the eigenvectors x_μ by means of the equations $(\lambda_\mu I - A)x_\mu = 0$. In methods of the second kind, one obtains eigenvalues and eigenvectors directly without resorting to the solution of an algebraic equation, relying instead upon repeated application of similarity transformations. (The power method does not fit into this classification, being a different approach altogether; \rightarrow Section C.) In particular, a real symmetric or complex Hermitian matrix is reduced approximately to a diagonal matrix. In this article we denote a given square matrix of order n by $A = (a_{ij})$ ($i, j = 1, \dots, n$).

B. The Jacobi Method

The Jacobi method is an iterative technique for determining all the eigenvalues and eigenvectors of a real symmetric matrix [7]. Before the advent of high-speed computers it was not considered practical, but at present it is one of the most compact and elegant methods. The following algorithm can be extended to Hermitian matrices by replacing †orthogonal transformations by suitable †unitary transformations.

Roughly, the method transforms a given matrix $A = (a_{ij})$ ($a_{ji} = a_{ij}$; $i, j = 1, \dots, n$) into a diagonal one by repeated application of 2-dimensional rotations of the reference axes. We first put $A^{(0)} = A$, $U^{(0)} = I$, and compute $A^{(1)}$, $A^{(2)}$, ..., $U^{(1)}$, $U^{(2)}$, ... successively as follows:

(1) Select an off-diagonal element of $A^{(0)} =$

($a_{ij}^{(0)}$) with the maximum absolute value and denote it by $a_{pq}^{(0)}$.

(2) Compute

$$\tan \theta = \frac{2a_{pq}^{(0)} \operatorname{sgn}(a_{pp}^{(0)} - a_{qq}^{(0)})}{|a_{pp}^{(0)} - a_{qq}^{(0)}| + \sqrt{(a_{pp}^{(0)} - a_{qq}^{(0)})^2 + 4(a_{pq}^{(0)})^2}}$$

(where $\operatorname{sgn} x = 1, 0$, or -1 according as $x > 0$,
 $= 0$, or < 0),

$$\cos \theta = (1 + \tan^2 \theta)^{-1/2}, \quad \text{and}$$

$$\sin \theta = \tan \theta \cdot \cos \theta;$$

and form $T^{(0)} = (t_{ij}^{(0)})$, where $t_{pp}^{(0)} = t_{qq}^{(0)} = \cos \theta$, $t_{ii}^{(0)} = 1$ for $i \neq p, q$, $-t_{pq}^{(0)} = t_{qp}^{(0)} = \sin \theta$, and $t_{ij}^{(0)} = 0$ for all other (i, j) .

(3) Determine $A^{(u+1)}$ and $U^{(u+1)}$ by $A^{(u+1)} = T^{(0)'} A^{(0)} T^{(0)}$ ($'$ denotes the transpose) and $U^{(u+1)} = U^{(0)} T^{(0)}$. In this process, $T^{(0)}$ represents an orthogonal transformation (rotation) in the plane spanned by the p th and q th coordinate axes such that $a_{pq}^{(u+1)} = a_{pq}^{(u+1)}$ is nullified. If we put $N(B) = \sum_{i,j} b_{ij}^2$ and $M(B) = \sum_{i \neq j} b_{ij}^2$, then $N(B)$ is invariant under an orthogonal transformation, so that $N(A^{(0)}) = N(A)$. Furthermore, since $a_{ii}^{(u+1)} = a_{ii}^{(0)}$ ($i \neq p, q$) and $(a_{pp}^{(u+1)})^2 + (a_{qq}^{(u+1)})^2 = (a_{pp}^{(0)})^2 + (a_{qq}^{(0)})^2 + 2(a_{pq}^{(0)})^2$, we have $M(A^{(u+1)}) = M(A^{(0)}) - 2(a_{pq}^{(0)})^2$. Since $a_{pq}^{(0)}$ has the maximum absolute value among all the off-diagonal elements, we have $(a_{pq}^{(0)})^2 \geq M(A^{(0)})/(n^2 - n)$. Therefore

$$\begin{aligned} M(A^{(u+1)}) &\leq (1 - 2/(n^2 - n)) M(A^{(0)}) \\ &\leq (1 - 2/(n^2 - n))^{u+1} M(A) \\ &< M(A) \exp(-2(u+1)/(n^2 - n)). \end{aligned}$$

It has been proved a fortiori [13] that, after $M(A^{(0)})$ comes down to below a certain threshold value, the convergence of the iteration process becomes quadratic, i.e., there is a number c determined by the order n of A and the arrangement of the eigenvalues of A such that $M(A^{(u+n(n-1)/2)}) < c(M(A^{(0)}))^2$. Since the set of eigenvalues of $A^{(0)}$ coincides with that of A and the eigenvalues of an arbitrary symmetric matrix B can be made to correspond in a one-to-one way to its diagonal elements in such a way that the difference between an eigenvalue and the corresponding diagonal element is not greater than $M(B)^{1/2}$, $a_{ii}^{(0)}$ tends to λ_i ($i = 1, \dots, n$) as l tends to infinity. Moreover, as l tends to infinity, each column vector of $U^{(0)} = (u_{ij}^{(0)})$ tends to the corresponding eigenvector, in the sense that $\sum_{k=1}^n a_{ik} u_{kj}^{(0)} - \lambda_j u_j^{(0)} \rightarrow 0$.

The number of arithmetic computations required to obtain $A^{(u+1)}$ and $U^{(u+1)}$ from $A^{(0)}$ and $U^{(0)}$ is at most proportional to n , so that for a given $\varepsilon > 0$, the arithmetic required to reduce $\max_i |a_{ii}^{(0)} - \lambda_i|$ below $\varepsilon(M(A))^{1/2}$ is at most proportional to n^3 (because l is at most

proportional to n^2). On the other hand, the search for an off-diagonal element of $A^{(i)}$ with the maximum absolute value, if it is done by simply comparing all the elements, will require effort proportional to n^2 , so that the amount of work required by the searching process is proportional to n^4 . To bypass this searching process, the **cyclic Jacobi method** and the **threshold Jacobi method** are often used. The former method adopts as $a_{pq}^{(i)}$ the off-diagonal element for which $q > p$ and $i = (p-1)(n-p/2) + (q-p)$, that is, $a_{12}^{(1)}, a_{13}^{(2)}, \dots, a_{1n}^{(n-1)}, a_{23}^{(n)}, a_{24}^{(n+1)}, \dots$ are adopted in this sequence. The latter method adopts as $a_{pq}^{(i)}$ off-diagonal elements in a sequence similar to the one above as long as they exceed a given threshold value; but if an element is less than that threshold value, then the next element in the sequence is a candidate for adoption as $a_{pq}^{(i)}$, where the threshold value is made to decrease gradually as the iteration process proceeds. However, the search for an element with the maximum absolute value can be done more effectively by taking account of the fact that only the matrix elements lying in rows p and q and in columns p and q change their values when we transform $A^{(i)}$ into $A^{(i+1)}$. In fact, we can record for each row the value as well as the position of the (off-diagonal) element with the maximum absolute value in that row. By so doing, the effort of searching for an off-diagonal element with the maximum absolute value can be reduced to something proportional to n on the average.

C. The Power Method

The **power method** is suitable for obtaining only the eigenvalue of maximum absolute value [6]. Let us assume that the eigenvalues $\lambda_1, \dots, \lambda_n$ of A are arranged so that $|\lambda_1| > |\lambda_2| \geq |\lambda_3| \geq \dots \geq |\lambda_n|$, with λ_1 real, and denote by y_1 the left eigenvector corresponding to λ_1 (which means $y_1(\lambda_1 I - A) = 0$). Starting from an arbitrary (real) vector $x^{(0)}$ such that $(y_1, x^{(0)}) \neq 0$ and $x_{i_0}^{(0)} = 1$ for a prescribed i_0 , we compute $\theta^{(0)}, \theta^{(1)}, \dots$ and $x^{(1)}, x^{(2)}, \dots$ by $Ax^{(i)} = \theta^{(i)} x^{(i+1)}$ ($i = 0, 1, 2, \dots; x_{i_0}^{(i+1)} = 1$). Then we have $\lim_{i \rightarrow \infty} \theta^{(i)} = \lambda_1$ and $\lim_{i \rightarrow \infty} x^{(i)} = x_1$ (the eigenvector corresponding to the eigenvalue λ_1). The rate of convergence depends on $|\lambda_1/\lambda_2|$ if the elementary divisor of A corresponding to λ_1 is linear, but in the case of a nonlinear elementary divisor, the convergence is too slow for practical purposes. If $\lambda_1 \neq \lambda_2$ and $|\lambda_1| = |\lambda_2| > |\lambda_3| \geq \dots \geq |\lambda_n|$, then the sequences of $\theta^{(i)}$ and $x^{(i)}$ computed by the formulas above do not converge but in general oscillate. However, from $\theta^{(i)}, \theta^{(i+1)}, x^{(i)}, x^{(i+1)}, x^{(i+2)}$ for a sufficiently large i , we can obtain

approximate eigenvalues λ_1 and λ_2 as the two roots of the quadratic equation in λ :

$$\begin{vmatrix} \chi_i^{(i)} & \chi_j^{(i)} & \theta^{(i)} \theta^{(i+1)} \\ \chi_i^{(i+1)} & \chi_j^{(i+1)} & \theta^{(i)} \lambda \\ \chi_i^{(i+2)} & \chi_j^{(i+2)} & \lambda^2 \end{vmatrix} = 0$$

(i and j arbitrary, $i \neq j$).

The corresponding eigenvectors are given by $x_1 = \lambda_2 x^{(i+1)} - x^{(i+2)}$ and $x_2 = \lambda_1 x^{(i+1)} - x^{(i+2)}$. Complex conjugate pairs of eigenvalues can be dealt with in this manner. This is useful also when $|\lambda_1| = |\lambda_2|$. The extension to the case of more than two eigenvalues with the same maximum absolute value is obvious.

In order to determine the remaining eigenvalues by the power method we have to combine it with the deflation or transformation of matrices, as discussed later in this section and in the following section. The amount of computation depends on the arrangement of the eigenvalues of A and the required accuracy. We note that the multiplication of a matrix by a vector requires an amount of computation proportional to n^2 .

Improvement in the approximations can be incorporated into the power method. If $v = x_\mu + O(\epsilon)$ is an approximation to the eigenvector x_μ corresponding to an eigenvalue λ_μ of a real symmetric matrix A , then the Rayleigh quotient $\lambda_R = (v, Av)/(v, v)$ affords a good approximation to λ_μ . In fact, we have $|\lambda_\mu - \lambda_R| = O(\epsilon^2)$.

If λ_i ($i = 1, \dots, n$) is an eigenvalue of A and x_i the corresponding eigenvector, then $P(\lambda_i)$ ($i = 1, \dots, n$) is an eigenvalue of $P(A)$ and x_i the corresponding eigenvector, where $P(\xi)$ is a polynomial in ξ and ξ^{-1} . This fact can be utilized to transform the magnitudes of eigenvalues to accelerate the convergence of the power method, to separate eigenvalues with the same absolute value, or to obtain intermediate eigenvalues. The choice $P(\lambda) = \lambda - c$ or $(\lambda - c)^{-1}$ is particularly useful, where c is an appropriate constant. In fact, an efficient algorithm known as **inverse iteration** exists for computing an approximate eigenvector when a good approximation to an eigenvalue is known. Given a trial eigenvector x corresponding to a computed eigenvalue c , one computes an improved approximate eigenvector y by solving $(A - cI)y = x$ or $y = (A - cI)^{-1}x$.

Aitken's δ^2 -method is also efficient in accelerating the convergence of the power method.

When an eigenvalue-eigenvector pair is known, another eigenvalue-eigenvector pair can be computed using the process known as **deflation**. If an eigenvalue λ_μ and the corresponding eigenvector x_μ (and also the corresponding left eigenvector y_μ if necessary) of A are known, it is possible to "subtract" them

from A to get a problem containing only the remaining eigenvalues. Such deflations are often used in combination with the power method. The following are two examples of deflation methods.

(1) Assuming that x_μ and y_μ are normalized in such a way that $(y_\mu, x_\mu) = 1$, form $B = A - \lambda_\mu x_\mu y_\mu'$. Then B has the same set of eigenvalues and eigenvectors as A except for λ_μ . The eigenvalue and the eigenvector of B corresponding to λ_μ of A are 0 and x_μ , respectively. This kind of deflation process can be generalized to the case of nonlinear elementary divisors, but that becomes somewhat more complicated.

(2) After normalizing x_μ so that its n th component $x_{\mu n}$ is equal to 1, form $B = (b_{ij})$; $b_{ij} = a_{ij} - x_{\mu i} a_{nj}$ ($i, j = 1, \dots, n-1$). Then B has the same set of eigenvalues as A except for λ_μ . If w_k is the eigenvector corresponding to the eigenvalue λ_k of B , then the corresponding eigenvector x_k of A is given by $x_{ki} = w_{ki} + d_k x_{\mu i}$ ($i = 1, \dots, n-1$), $x_{kn} = d_k$, where d_k is determined from $\sum_{i=1}^{n-1} n_i w_{ki} = (\lambda_k - \lambda_\mu) d_k$ if $\lambda_k \neq \lambda_\mu$. If $\lambda_k = \lambda_\mu$ and $r \equiv \sum_{i=1}^{n-1} a_{ni} w_{ki} = 0$, then we can put $d_k = 0$. If $\lambda_k = \lambda_\mu$ and $r \neq 0$, A has a nonlinear elementary divisor for $\lambda_k = \lambda_\mu$, and the x_k defined by $x_{ki} = w_{ki}/r$ and $x_{kn} = 0$ is a generalized eigenvector of A in the sense that $Ax_k = \lambda_\mu x_k + x_\mu$.

D. Transformation of Matrices

There are a number of methods of transforming a given matrix A by means of a suitable similarity transformation $A \rightarrow B = S^{-1}AS$ into another matrix B for which it is easier to solve the eigenvalue problem. The **Givens method** [9] transforms a symmetric matrix A into a **tridiagonal matrix** B (i.e., a matrix such that $b_{ij} = 0$ for $|i-j| \geq 2$) by means of a matrix S which is the product of 2-dimensional rotation matrices. The **Householder method** [10] also transforms a symmetric A into a tridiagonal B by means of an orthogonal matrix S of special type, i.e., a reflection matrix $I - 2uu^*$ ($u^*u = 1$, $u^* =$ conjugate transpose of u), and the **Lanczos method** [8] transforms a general A into a tridiagonal B . To general matrices the following methods are also applicable: (1) The **Danilevskii method** [1] transforms A into its companion matrix B by repeated application of elimination operations. Here, row interchanges can be combined to increase numerical stability [14]. (2) The **Hessenberg method** [3] transforms A into a B such that $b_{ij} = 0$ for $i-j \geq 2$ with a triangular S . (3) The Givens method [9] transforms A into a B of the same form as in (2) by repeated application of 2-dimensional rotations. This method now tends to give way to the Householder method or to

the elimination method with row interchange. All these methods require an amount of computation proportional to n^3 . In general, special treatment is necessary for the case of multiple eigenvalues. As an example, we explain the Givens method for general matrices. Let $N = (n-1)(n-2)/2$. For $i = 0, 1, \dots, N-1$, choose $(p, q) = (3, 2), (4, 2), \dots, (n, 2); (4, 3), (5, 3), \dots, (n, 3); \dots; (n-1, n-2), (n, n-2); (n, n-1)$ in this order. Using $T^{(i)}$ of the same form as in the Jacobi method, and setting $\tan \theta = a_{p,q-1}^{(i)}/a_{q,q-1}^{(i)}$ in this case, calculate $A^{(0)} = A$, $U^{(0)} = I$, $A^{(i+1)} = T^{(i)'} A^{(i)} T^{(i)}$, $U^{(i+1)} = U^{(i)} T^{(i)}$ ($i = 0, 1, \dots, N-1$), and put $B = A^{(N)}$. Then we have $b_{ij} = 0$ for $i-j \geq 2$. We can solve the eigenvalue problem for this simplified B and then retransform the eigenvectors of B thus obtained into those of A by means of $U^{(N)}$. It should be noted that the method of bisection based on Sturm's theorem is effectively used to solve the characteristic equation of a real tridiagonal matrix [14]. This method is remarkably stable numerically. It is used when the number of eigenvalues to be computed is small relative to the order of the given matrix. If all eigenvalues are desired, an alternative method such as the QR method (\rightarrow Section F) is recommended.

E. The Lanczos Method

A more detailed exposition of the Lanczos method is now given. Let A be a given real matrix of order n . Pick two vectors c_1 and \tilde{c}_1 . Determine recursively the vectors c_{i+1} and \tilde{c}_{i+1} , $i = 1, \dots, n$, that satisfy the following conditions: (i) $\gamma_{i+1} c_{i+1} = A c_i - \alpha_i c_i - \beta_i c_{i-1} \equiv b_{i+1}$, $\tilde{\gamma}_{i+1} \tilde{c}_{i+1} = A' \tilde{c}_i - \tilde{\alpha}_i \tilde{c}_i - \tilde{\beta}_i \tilde{c}_{i-1} \equiv \tilde{b}_{i+1}$, $i = 2, \dots, n$; (ii) c_{i+1} is orthogonal to \tilde{c}_{i-1} and \tilde{c}_i ; (iii) \tilde{c}_{i+1} is orthogonal to c_{i-1} and c_i , where $\alpha_i, \beta_i, \tilde{\alpha}_i$, and $\tilde{\beta}_i$ are scalars, and where γ_i and $\tilde{\gamma}_i$ are normalizing scalars. Actually, $\alpha_i = \tilde{c}_i' A c_i / \tilde{c}_i' c_i = \tilde{\alpha}_i$, $\beta_i = \gamma_i \tilde{c}_i' \tilde{c}_i / \tilde{c}_{i-1}' c_{i-1}$, $\tilde{\beta}_i = \gamma_i \tilde{c}_i' c_i / c_{i-1}' \tilde{c}_{i-1}$, where $c_i' \tilde{c}_i$, $i = 1, \dots, n$, are assumed nonzero. It can be shown that c_{i+1} is orthogonal to every \tilde{c}_j , $1 \leq j \leq i$, and that \tilde{c}_{i+1} is orthogonal to every c_j , $1 \leq j \leq i$ ($c_{n+1} = \tilde{c}_{n+1} = 0$). The conclusion is that the given matrix A is similar to the tridiagonal matrix $H = (h_{ij})$, where $h_{ii} = \alpha_i$ ($i = 1, \dots, n$), $h_{i,i+1} = \beta_{i+1}$, $h_{i+1,i} = \tilde{\gamma}_{i+1}$ ($i = 2, \dots, n$). In fact, if C denotes the matrix whose j th column equals c_j ($j = 1, \dots, n$), one obtains $C^{-1}AC = H$. Thus the eigenvalues of A are identical to those of H .

In principle, the Lanczos method transforms a given matrix to a tridiagonal matrix similar to it if every $c_i' \tilde{c}_i$ is nonzero ($i = 1, \dots, n$). If $c_i' \tilde{c}_i$ does vanish for a certain i , one selects c_1 and \tilde{c}_1 again and restarts. On the other hand, if $b_{i+1} = 0$ one chooses an arbitrary vector c_{i+1} orthogonal to $\tilde{c}_1, \dots, \tilde{c}_i$ and if $\tilde{b}_{i+1} = 0$ one selects an arbitrary vector \tilde{c}_{i+1} orthogonal to

c_1, \dots, c_i . In the actual numerical computation, the distinction between zero vectors and non-zero vectors is usually blurred by rounding errors.

In the application of the Lanczos method one often observes the loss of orthogonality $c_i^T \tilde{c}_j = 0$ ($i \neq j$). This usually results from cancellation errors in the computation of b_{i+1} and \tilde{b}_{i+1} . If the orthogonality is lost, $C^{-1}AC$ may significantly deviate from a tridiagonal matrix. As a practical means for preserving the indicated orthogonality one can reorthogonalize the vectors c_i and \tilde{c}_i . Indeed, one can add to the computed c_{i+1} a linear combination of c_1, \dots, c_i so that the sum is orthogonal to $\tilde{c}_1, \dots, \tilde{c}_i$, then take the sum as c_{i+1} after properly normalizing. A similar process applies to \tilde{c}_{i+1} . The Lanczos method is often applied in double precision. It has been suggested that one first reduces the given matrix to an upper Hessenberg form by using the Hessenberg method with row interchange before applying the Lanczos method [15].

A further remark on the Lanczos method is in order. Recall that γ_i is determined from $Ac_i, c_{i-1}, \alpha_{i-1}$, and β_{i-1} ; β_i from $c_i, \tilde{c}_i, c_{i-1}, \tilde{c}_{i-1}$, and $\tilde{\gamma}_i$; and α_i from Ac_i, c_i , and \tilde{c}_i . This shows that the Lanczos method applied to a sparse matrix (a matrix whose elements are almost all zero) requires only a memory proportional to n . The Householder method, on the other hand, requires memory proportional to n^2 even for a sparse matrix.

For a real symmetric matrix one can modify the Lanczos method for a general matrix so that C is orthogonal and H is real, symmetric, and tridiagonal (the details are omitted).

F. The QR Method

The QR method was discovered independently by J. G. F. Francis and by V. N. Kublanovskaya in 1961 [15]. The method has been improved and extended considerably since then. In the usual application to matrix eigenvalue problems, the QR method provides the most efficient iterative process for finding all eigenvalues of a given matrix. The matrix is reduced by means of a similarity transformation to Hessenberg form or to tridiagonal form before application of the QR method; the reduction process may be effected by the Householder method or by the elimination method with row interchange. (If the given matrix is a complex matrix, the latter is preferable.) The reason is that one step of the QR process applied to a full matrix is prohibitively expensive, requiring a number of operations propor-

tional to n^3 , while one step of the QR process applied to a Hessenberg matrix requires a number of operations proportional to n^2 .

We now describe one of the most useful versions of the QR method. Let $A = A_0$ be a given matrix, and define a sequence of matrices A_1, A_2, \dots obtained from A_0 as follows. At the i th ($i = 0, 1, \dots$) step, choose an appropriate constant s_i , called an origin shift, according to the process described below, and decompose $A_i - s_i I$ into the product of a unitary matrix Q_i and an upper Hessenberg matrix R_i : $A_i - s_i I = Q_i R_i$. The matrix A_{i+1} is then defined by $A_{i+1} = R_i Q_i + s_i I = Q_i^* A_i Q_i$. Hence A_{i+1} is similar to A_i . The QR method is closely related to the power method and to the inverse power method. We describe this relationship in order to obtain an insight into the nature of the QR method. To this end, we first state a well-known theorem: Let A be diagonalizable, and let its eigenvalues λ_i ($i = 1, \dots, n$) have distinct moduli, say $|\lambda_1| > |\lambda_2| > \dots > |\lambda_n|$. Let $X^{-1}AX = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_n\}$, and let X have an LU-decomposition $X = LU$, where L and U are, respectively, lower triangular matrix and an upper triangular matrix. Then the QR algorithm without an origin shift ($s_i = 0, i = 0, 1, 2, \dots$) behaves as follows: $a_{pq}^{(i)} \rightarrow 0$ ($p > q$); $a_{pp}^{(i)} \rightarrow \lambda_p$; $a_{pq}^{(i)}$ oscillates ($p < q$), $p, q = 1, 2, \dots, n, i \rightarrow \infty$, where $a_{pq}^{(i)}$ denotes the (p, q) th element of A_i . In other words, A_i approaches an upper triangular matrix as $i \rightarrow \infty$ so that the diagonal elements of A_i converge to the eigenvalues of A .

The relationship between the QR algorithm and the power method is given by $(Q_0 Q_1 \dots Q_i)(R_i R_{i-1} \dots R_0) = (A - s_0 I)(A - s_1 I) \dots (A - s_i I)$. If $s_0 = s_1 = \dots = s_i = 0$, then the right-hand side reduces to A^{i+1} , and since the product $R_i \dots R_0$ is upper triangular, the first column of $\tilde{Q}_i \equiv Q_0 Q_1 \dots Q_i$ equals a scalar multiple of $A^{i+1} e_1$, where $e_1 = (1, 0, 0, \dots, 0)^T$. Therefore, by the power method, the first column of \tilde{Q}_i converges to an eigenvector corresponding to the eigenvalue λ_1 of A that has the largest modulus, under a certain fairly mild condition. Since $A_{i+1} = \tilde{Q}_i^* A \tilde{Q}_i$, $A_{i+1} e_1 = \tilde{Q}_i^* A \tilde{Q}_i e_1 \approx \lambda_1 e_1$ for large i . In other words, the first column of A_i converges to the vector $(\lambda_1, 0, 0, \dots, 0)^T$ as $i \rightarrow \infty$.

The relationship of the QR method to the inverse power method and to the Rayleigh quotient is now explained. From the definition of the QR algorithm with an origin shift, we have $Q_i = [(A - s_i I)^{-1}]^* R_i^*$. Since R_i^* is a lower triangular matrix, the n th column of Q_i equals $Q_i e_n = [(A_i - s_i I)^{-1}]^* R_i^* e_n = (A - s_i I)^{-1} \cdot$ (a scalar multiple of e_n), where $e_n = (0, 0, \dots, 0, 1)^T$. This last process of obtaining the last column of Q_i represents a process known as the inverse power method. If s_i is close to an eigenvalue of

A_i (and hence to an eigenvalue of A), the last column of A_i gives a good approximate eigenvector of A corresponding to the eigenvalue under consideration. Now, if x is a given column vector such that $x^*x = 1$, the value of λ which minimizes $(Ax - \lambda x)^*(Ax - \lambda x)$ is given by the Rayleigh quotient x^*Ax . If $x(x^*x = 1)$ happens to be an eigenvector of A , the Rayleigh quotient equals an eigenvalue of A . If we take $x = e_n$, the corresponding Rayleigh quotient equals a_{nn} . Therefore if we take the (n, n) th element of A_i as the origin shift s_i , then s_i can be regarded as the best approximation to an eigenvalue of A_i (hence of A) when e_n is taken as an approximate eigenvector of A_i , in the sense that $\lambda = s_i$ minimizes the functional $(A_i e_n - \lambda e_n)^*(A_i e_n - \lambda e_n)$.

Under the same condition as in the preceding theorem, the rate of convergence of the QR method with an origin shift is given as follows: $a_{pq}^{(i)} (n \geq p \geq q \geq 1)$ is asymptotically proportional to $(\lambda_p/\lambda_q)^i$ for $s_i = 0$ ($i = 0, 1, \dots$) (no origin shift); and with the origin shift s_i , the behavior of $a_{pq}^{(i)}$ at the i th step is determined by $(\lambda_p - s_i)/(\lambda_q - s_i)$. If $s_i = \lambda_n$ (= the eigenvalue of A with the least modulus), each element in the n th row of A_{i+1} except $a_{nn}^{(i+1)}$ exhibits rapid decrease in modulus. A natural and practical choice of the origin shift s_i is given as follows: (i) for a real tridiagonal matrix, s_i is taken to be that eigenvalue of the 2×2 matrix situated at the lower right corner of A_i that is closer to $a_{nn}^{(i)}$ [14]; (ii) for a real upper Hessenberg matrix, the two eigenvalues of the 2×2 matrix situated at the lower right corner of A_i as s_i and s_{i+1} [14]; (iii) for a complex upper Hessenberg matrix, s_i is chosen as in (i) [17, COMQR].

The QR method with origin shift would eventually make each element in the n th row, except $a_{nn}^{(i)}$, smaller in modulus than a prescribed positive number. At this stage of iteration, $a_{nn}^{(i)}$ is taken as an approximate eigenvalue of A . The QR method is then applied anew to the $(n-1) \times (n-1)$ matrix obtained from A_i by deleting the n th row and the n th column of A_i , and another approximate eigenvalue of A is obtained. The method proceeds similarly until all the eigenvalues of A are computed. For maximum accuracy the eigenvalues of the given matrix should be computed in the order of increasing modulus. A word of caution is in order. When the given matrix A has elements of greatly varying modulus, rearrangement of elements of A may be necessary before applying the QR method with an explicit origin shift, where $A_i - s_i I$ ($i = 0, 1, \dots$) is explicitly computed.

The reader is referred to [14–16] for details of the QR method.

G. Generalized Eigenvalue Problem $Ax = \lambda Bx$

An eigenvalue problem of the type $Ax = \lambda Bx$ is called a **generalized eigenvalue problem** and is often encountered in applied mathematics. A necessary and sufficient condition for λ to be an eigenvalue is $\det(A - \lambda B) = 0$. If B^{-1} exists, then $Ax = \lambda Bx$ is equivalent to $B^{-1}Ax = \lambda x$ and hence has n eigenvalues, where n is the order of A . If B^{-1} does not exist, the eigenvalue problem $Ax = \lambda Bx$ has at most $n-1$ eigenvalues.

We restrict ourselves to one of the most important cases: that where A is real and symmetric and B is real, symmetric, and positive definite. In this case one could solve the problem by reformulating it as $B^{-1}Ax = \lambda x$, where $B^{-1}A$ is explicitly computed. However, $B^{-1}A$ is not in general symmetric. Moreover, when B has eigenvalues of widely different moduli, the elements of B^{-1} may have widely different moduli as well, which would in turn make the computation of those eigenvalues of $B^{-1}A$ of smaller moduli difficult. An efficient and numerically stable method is known which obviates the aforementioned difficulty by exploiting the symmetry of A and B . An outline of this procedure is now given. Since B is positive definite, a lower triangular matrix L exists such that $LL' = B$. This is called the Cholesky decomposition of B . The elements of L can be computed by equating the corresponding elements in $LL' = B$. The eigenvalue problem $Ax = \lambda Bx$ is now equivalent to $L^{-1}A(L')^{-1}y = \lambda y$ with $y = L'x$, where the matrix $L^{-1}A(L')^{-1} = P$ is computed in two stages by solving $LX = A$ and $PL' = X$. In this last equation it is enough to compute the upper right half of P , because P is symmetric while X is not generally symmetric. The upper right half of P can be computed by equating the corresponding elements in $PL' = X$. The eigenvalues λ of $Ax = \lambda Bx$ are given by the eigenvalues of the matrix P . Other types of eigenvalue problems, such as $y'AB = \lambda y'$, $BAy = \lambda y$, and $x'BA = \lambda x'$, often appear in practice, where A is real and symmetric and B is real, symmetric, and positive definite. By using the Cholesky decomposition of B , one can reduce any one of these eigenvalue problems to the ordinary eigenvalue problem for a real symmetric matrix [4].

If A and B are general matrices in $Ax = \lambda Bx$, the following method is known to be effective [18]. First, reduce B to an upper triangular matrix by applying $n-1$ Householder transformations from the left. This reduces the eigenvalue problem $Ax = \lambda Bx$ to the case where B is upper triangular. Next, apply to A a sequence of plane rotations of Givens type from the left, thereby reducing the eigenvalue problem $Ax = \lambda Bx$ to the case where A is an

Numerical Computation of Eigenvalues

upper Hessenberg matrix and B is an upper triangular matrix. Then apply the QR method to $B^{-1}Ax = \lambda x$ without explicitly computing $B^{-1}A$ to reduce the eigenvalue problem $Ax = \lambda Bx$ to the case where A and B are both approximately upper triangular. The eigenvalues of $Ax = \lambda Bx$ are then easily computed as ratios of corresponding diagonal elements. This method is called the **QZ method** [18].

A collection of about 50 excellent FORTRAN subroutines for various types of matrix eigenvalue problems is contained in [18]. These subroutines are in most part translations from ALGOL procedures given in [14].

299 (XV.7) Numerical Integration

A. Interpolatory Integration Formulas

Numerical integration is a method of finding an approximate numerical value of a definite integral of a given function $f(x)$. Usually the integral $\int_a^b f(x)dx$ or $\int_a^b f(x)w(x)dx$ ($w(x)$ is the **weight function**) is approximated by a linear combination $\sum_{i=1}^n W_i f(x_i)$ of the values of the integrand at the points x_1, x_2, \dots, x_n . Integration formulas are divided into two groups, the interpolatory formulas and the formulas based on variable transformation.

In order to obtain an **interpolatory formula**, we interpolate over the integrand $f(x)$ at n points x_1, x_2, \dots, x_n by means of the † Lagrange interpolation polynomial of degree $n-1$, and then integrate the polynomial over $[a, b]$. Depending on the selection of the points x_i and the weights W_i , we have several kinds of formulas.

(1) Newton-Cotes Formulas. We assume $w(x) = \text{constant}$ and $x_i = x_0 + ih$ ($i = 0, 1, \dots, n$). The weights W_i are so determined that the value of the integral can be calculated accurately if the integrand $f(x)$ is a polynomial whose degree does not exceed n . There formulas are called the **Newton-Cotes formulas**: $\int_{x_0}^{x_1} f(x)dx = (f_0 + f_1)h/2$ for $n = 1$ (**trapezoidal rule**), $\int_{x_0}^{x_2} f(x)dx = (f_0 + 4f_1 + f_2)h/3$ for $n = 2$ (**Simpson's 1/3 rule**), and $\int_{x_0}^{x_3} f(x)dx = (f_0 + 3f_1 + 3f_2 + f_3)3h/8$ for $n = 3$ (**Simpson's 3/8 rule**). The truncation errors of these three formulas are given by $h^3 f^{(2)}(\xi)/12$, $h^5 f^{(4)}(\xi)/90$, $3h^5 f^{(4)}(\xi)/80$, respectively, where ξ is a number in the interval of integration and $f^{(i)}$ denotes the i th derivative of f (differentiability is assumed). For an even n , the polynomial of degree $n+1$ can also be integrated accurately by these formulas.

In Table 1 the coefficients A and B_i of the Newton-Cotes formulas $hA \sum_{i=0}^n B_i f(x_i)$, $h = (x_n - x_0)/n$, and the coefficients C of the error

Table 1

term $Ch^{p+1}f^{(p)}(\xi)$, where $p = n + 2$ if n is even and $p = n + 1$ if n is odd, are given.

When the interval $[a, b]$ of integration is large, we usually divide it into small subintervals and apply formulas for small n for each part rather than formulas for large n for the whole interval. For example, if the interval is divided into m equal subintervals, we get the following formula by applying the trapezoidal rule for each subinterval:

$$\int_a^b f(x)dx = h((f_0 + f_m)/2 + (f_1 + f_2 + \dots + f_{m-1})),$$

where $x_0 = a$, $x_m = b$, $h = (b - a)/m$, with truncation error $(b - a)^3 f^{(2)}/(12m^2)$. (Here, as in the rest of the article, $f^{(i)}$ stands for $f^{(i)}(\xi)$, with differentiability assumed as before.) By applying Simpson's 1/3 rule we obtain the formula

$$\begin{aligned} \int_a^b f(x)dx \\ = \frac{2}{3}h((f_0 + f_{2m})/2 + 2(f_1 + f_3 + \dots + f_{2m-1}) \\ + (f_2 + f_4 + \dots + f_{2m-2})), \end{aligned}$$

where $x_0 = a$, $x_{2m} = b$, $h = (b - a)/2m$, with truncation error $(b - a)^5 f^{(4)}/180(2m)^4$.

For the integral of a periodic analytic function over a single period the trapezoidal rule with equally spaced points gives the best result asymptotically, as the number of points tends to infinity.

Newton-Cotes formulas can also be obtained by integrating over the interval $[a, b]$ the interpolation polynomial for equally spaced points. The formulas mentioned so far are called **closed formulas** since they use values at the two endpoints of the interval. We can also use **open formulas**, which do not use values at the ends. For example, we have $\int_{x_0}^{x_4} f(x)dx = 4h(2f_1 - f_2 + 2f_3)/3$ with truncation error $14h^5 f^{(4)}/45$. Open formulas are useful for numerical solution of differential equations. There are also formulas that include values outside the interval, for example, $(-f_{-1} + 13f_0 + 13f_1 - f_2)h/24$ for $\int_{x_0}^{x_1} f(x)dx$. Applying these formulas to the m subintervals of $[a, b]$, we obtain a trapezoidal formula with

the correction term $h(f_1 - f_{-1})/24 + h(f_m - f_{m+1})/24 = h(\Delta f_0 + \Delta f_{-1})/24 - h(\Delta f_{m-1} + \Delta f_m)/24$, where Δf_i means $f_{i+1} - f_i$.

(2) Chebyshev Formulas. The Chebyshev formulas are a family of integration formulas in which all the weights W_i of $\sum_{i=1}^n W_i f(x_i)$ are equal, while the abscissas x_i are chosen so that the integral can be evaluated exactly when $f(x)$ is an arbitrary polynomial whose degree does not exceed n . When $\int_{-1}^1 f(x)dx = W \sum_{i=1}^n f(x_i)$, it is easy to see that $W = 2/n$ since the right-hand side must be equal to the left-hand side when $f(x) \equiv 1$. It is known that the abscissas x_i for $n \leq 7$ and $n = 9$ are real, while for $n = 8$ and $n \geq 10$ at least one of the abscissas becomes complex. It is easy to see that Chebyshev formulas are interpolatory.

(3) Gauss Formulas. In the Gauss formulas both the weights W_i and the abscissas x_i are chosen so that we obtain the accurate value of the integral when the integrand is any polynomial whose degree does not exceed $2n - 1$. If we put $\Pi(x) = \prod_{i=1}^n (x - x_i)$, an arbitrary polynomial of degree $2n - 1$ can be expressed in the form

$$f(x) = \sum_{k=1}^n \frac{\Pi(x)}{(x - x_k)\Pi'(x_k)} f_k + \Pi(x) \sum_{k=0}^{n-1} a_k x^k,$$

where $f(x_k) = f_k$ and the first term is the †Lagrange interpolation polynomial. By the assumption that the integral of $f(x)$ with weight $w(x)$ equals $\sum_{k=1}^n W_k f_k$, we obtain $W_k = \int_a^b (w(x)\Pi(x)/(x - x_k)\Pi'(x_k))dx$ and the relations

$$\int_a^b w(x)\Pi(x)x^k dx = 0, \quad k = 0, 1, \dots, n - 1.$$

Accordingly, the abscissas x_i are determined as the roots of the polynomial $\Pi(x)$ of degree n that is orthogonal to x^k ($k = 0, 1, \dots, n - 1$) with respect to the weight function $w(x)$.

The following are typical examples of integration formulas of Gaussian type.

(i) **Gauss integration formulas** (in the narrow sense). For $w(x) = 1$ and the interval $[-1, 1]$, $\Pi(x)$ is the †Legendre polynomial $P_n(x) = (1/2^n n!)d^n(x^2 - 1)^n/dx^n$. The error is $(n!)^4 2^{2n+1} f^{(2n)}/(2n + 1)((2n)!)^3$.

(ii) **Gauss-Laguerre formulas.** For the weight $w(x) = \exp(-x)$ and the interval $[0, \infty)$, $\Pi(x)$ is the † Laguerre polynomial $L_n(x) = (\exp x) d^n (x^n \exp(-x)) / dx^n$.

(iii) **Gauss-Hermite formulas.** For the weight function $w(x) = \exp(-x^2)$ and the interval $(-\infty, \infty)$, $\Pi(x)$ is the † Hermite polynomial $H_n(x) = (-1)^n \exp x^2 \cdot d^n \exp(-x^2) / dx^n$.

(iv) **Gauss-Chebyshev formulas.** For the weight function $w(x) = (1 - x^2)^{-1/2}$ and the interval $[-1, 1]$, we use the Chebyshev polynomial $T_n(x) = 2^{-(n-1)} \cos(n \arccos x)$. In this case, the W_i are all equal to π/n .

From the definition of W_k we see that the Gauss formulas are interpolatory.

(4) **Clenshaw-Curtis Formulas.** Although the Gauss formula is in general more accurate than the Newton-Cotes formula with the same number of points of interpolation, the points of interpolation for a Gauss formula of any order are distinct from those of any other order except the point zero, which appears in all formulas of odd order. The **Clenshaw-Curtis formulas** are interpolatory, with the points chosen so that the distribution of the points is similar to that of the Gauss formula and such that, in proceeding from a computation of order n to that of order $2n$, all the function values evaluated in the former computation be used in the latter. For $w(x) = 1$, the interval $[-1, 1]$, and even n , the points x_k and the weights W_k are given by

$$x_k = \cos \frac{k\pi}{n}, \quad k = 0, 1, \dots, n;$$

$$W_0 = W_n = \frac{1}{n^2 - 1};$$

$$W_s = W_{n-s} = \frac{4}{n} \sum_{j=0}^{n/2} \frac{1}{1 - 4j^2} \cos \frac{2\pi js}{n},$$

$$s = 1, 2, \dots, \frac{n}{2}.$$

Σ'' means that the first and the last terms in the sum are to be halved. There are some different types of Clenshaw-Curtis formulas depending on the selection of the points x_k [1].

B. Integration Formulas Based on Variable Transformation

If the integrand has some singularity at the endpoint, any interpolatory formula based on interpolation with a polynomial does not give a good result. In such cases **integration formulas based on variable transformation** are quite effective.

(1) **IMT Formula.** The † Euler-Maclaurin formula is given by

$$\int_a^b f(x) dx = h \left\{ \frac{1}{2} f(a) + \sum_{k=1}^{n-1} f(a + kh) + \frac{1}{2} f(b) \right\} \\ - \sum_{r=1}^m \frac{h^{2r} B_{2r}}{(2r)!} \{ f^{(2r-1)}(b) \\ - f^{(2r-1)}(a) \} + R_m,$$

$$h = \frac{b-a}{n},$$

$$R_m = \frac{h^{2m+1}}{(2m)!} \int_0^1 B_{2m}(t) \left\{ \sum_{k=0}^{n-1} f^{(2m)}(a + kh + ht) \right\} dt,$$

where the $B_n(t)$ are † Bernoulli polynomials of degree n and the B_n are † Bernoulli numbers ($B_0 = 1, B_1 = -1/2, B_2 = 1/6, B_3 = 0, B_4 = -1/30, \dots$). This formula suggests that if the higher derivatives of the integrand vanish at the both endpoints, the error of the trapezoidal rule with equally spaced points becomes very small. The **IMT formula** is based on the idea of transforming the variable x of $\int_0^1 f(x) dx$ in such a way that all the derivatives of the new integrand vanish at both endpoints by taking $x = \varphi(t)$, $\varphi(t) = K^{-1} \int_0^t \psi(\tau) d\tau$, $K = \int_0^1 \psi(\tau) d\tau$, $\psi(\tau) = \exp(-\tau^{-1} - (1-\tau)^{-1})$. Then the trapezoidal rule with $h = 1/n$ is applied to the transformed integral to obtain $(1/Kn) \sum_{j=1}^n \psi(j/n) f(\varphi(j/n))$ [1]. The asymptotic expression of the error for the IMT formula is proportional to $\exp(-C\sqrt{n})$ with a positive constant C .

(2) **Double Exponential Formula.** The trapezoidal rule with equally spaced points applied to the integral of an analytic function over $(-\infty, \infty)$ gives in general a result of high accuracy. The **double exponential formula** is based on the idea of transforming $\int_{-1}^1 f(x) dx$ to $\int_{-\infty}^{\infty} f(\varphi(t)) \varphi'(t) dt$ with $x = \varphi(t) = \tanh(\frac{1}{2} \pi \sinh t)$ and applying the trapezoidal rule with a mesh size h , which results in $h \sum_{n=-\infty}^{\infty} f(\varphi(nh)) \varphi'(nh)$ [4]. The name of the double exponential formula is attributed to the decay of $\varphi'(t)$ at $t \rightarrow \pm \infty$, which is approximately proportional to $\exp(-C \exp|t|)$ with a positive constant C . The transformations $x = \exp(\pi \sinh t)$ and $x = \sinh(\frac{1}{2} \pi \sinh t)$ give the double exponential formulas for the infinite integrals $\int_0^{\infty} f(x) dx$ and $\int_{-\infty}^{\infty} f(x) dx$, respectively. In the actual computation the infinite summation is truncated at appropriate upper and lower bounds. The asymptotic expression of the error for the double exponential formula in terms of the number N of the sampling points actually used is proportional to $\exp(-CN/\log N)$ with a positive constant C . The IMT formula and the double exponential

formula are robust against the singularities at the endpoints.

C. Automatic Integration

By an **automatic integration scheme** we mean a computer program for numerical integration of $\int_a^b f(x)dx$ in which the user gives the limits of integration a and b , a subroutine for computing $f(x)$, and an error tolerance ε . Then the program gives a value of the integral which is expected to be correct within the tolerance ε . Usually in an automatic integration scheme the mesh size is halved until the desired accuracy is attained. Automatic integration schemes are classified into two groups, nonadaptive schemes and adaptive schemes. In a **nonadaptive scheme**, the sequence of integration points is chosen according to some fixed rule independent of the shape of the integrand. Newton-Cotes formulas, Clenshaw-Curtis formulas, IMT formulas, and double exponential formulas can be used as base formulas for nonadaptive schemes.

From the historical point of view, **Romberg integration** should be mentioned; it is a kind of nonadaptive automatic integrator. Consider an integral $I = \int_a^b f(x)dx$. Divide the interval $[a, b]$ of integration into 2^k subintervals and apply the trapezoidal rule with the mesh size $h = (b-a)/2^k$, which we denote by $T_0^{(k)}$. Then, starting from the values obtained for $T_0^{(k)}$, $k=0, 1, \dots$, we compute the sequence

$$T_m^{(k)} = \frac{4^m T_{m-1}^{(k+1)} - T_{m-1}^{(k)}}{4^m - 1}, \quad m = 1, 2, \dots$$

From the † Euler-Maclaurin formula the asymptotic error for the trapezoidal rule $T_0^{(k)}$ can be expressed as $I - T_0^{(k)} = c_1 h^2 + c_2 h^4 + \dots + c_m h^{2m} + \dots$, where $c_m = \text{const} \times (f^{(2m-1)}(b) - f^{(2m-1)}(a))$ does not depend on h . If we compute $T_1^{(k)} = (4T_0^{(k+1)} - T_0^{(k)})/3$ using the values $T_0^{(k+1)}$ and $T_0^{(k)}$, then we see that the asymptotic error expression of $T_1^{(k)}$ becomes $I - T_1^{(k)} = c'_2 h^4 + c'_3 h^6 + \dots + c'_m h^{2m} + \dots$. Romberg integration is based on the idea of eliminating the term with h^{2m} in the expression of the error by successive application of $T_m^{(k)}$. This is an application of Richardson's extrapolation procedure.

In the **adaptive scheme**, the points are chosen in a way that depends on the shape of the integrand. The Newton-Cotes formula of order 8, for example, is used as the base formula for the adaptive scheme.

D. Approximate Multiple Integration

If a region is a product region, such as a rectangular parallelepiped, a **product rule** ob-

299 Ref.

Numerical Integration

tained by forming the product of 1-dimensional formulas is useful. For integrals over a cube or a sphere there are monomial rules which are exact for a certain family of monomials. These rules can be used for integrals of dimension lower than 5 or 6. For integrals of higher dimension only methods based on sampling make sense.

E. Numerical Differentiation

In order to find the numerical value of the derivative $f'_p = f'(x_p)$ at a point x_p from the tabulated values $f_k = f(x_k)$, we usually use the derivative of the † Lagrange interpolation formula. This gives

$$f'_p = \sum_{k \neq p} \frac{\Pi'(x_p)}{(x_p - x_k)\Pi'(x_k)} f_p + \sum_{k \neq p} \frac{1}{x_p - x_k} f_k,$$

where $\Pi(x) = \prod_{k=1}^n (x - x_k)$.

When we compute the derivative of a function which can be evaluated at any point in a given interval, the approximation

$$f'(x) = \frac{f(x+h) - f(x-h)}{2h}$$

is useful; similarly, we can use

$$f''(x) = \frac{f(x+h) - 2f(x) + f(x-h)}{h^2}.$$

It must be noted that, as h tends to zero, the difference $f(x+h) - f(x-h)$ comes to contain fewer significant digits, so that it is meaningless to carry out $\{f(x+h) - f(x-h)\}/2h$ beyond a reasonable value of h .

300 (XV.1) Numerical Methods

In the earlier history of mathematics, the development of methods of numerical calculation was one of the main purposes of research. Until the beginning of this century, logarithmic calculation played a central role in numerical calculation, and the main topic of this field was to make tables of values of functions. The digital electronic computer (\rightarrow 75 Computers), which made its first appearance in the 1940s and has been developing at an exponential rate, has caused drastic changes in numerical technique. Problem solving by numerical methods has now become one of the fundamental means of research in the physical sciences and engineering, and also in the social sciences and humanities. In this article we give examples of the changes in numerical methods brought about by the availability of digital computers and portable calculators.

Computers may be effectively utilized for calculating individual values of functions. This has led to the reexamination and, in some cases, modification of approximate formulas for evaluating functions (\rightarrow 142 Evaluation of Functions). For familiar functions, such as \dagger logarithmic, \dagger exponential, and \dagger trigonometric functions, tables have been almost completely replaced by function keys on electronic calculators. Microprogramming algorithms for obtaining values of these functions have also been devised [1]. A complex function-theoretic error-estimation method for use with numerical integration formulas is given in [2]. In this method, graphical outputs of the computer are utilized. For problems in which the existence and uniqueness of solutions have been established, as for algebraic equations and ordinary differential equations, fairly good numerical calculation methods and their error estimates have been established (\rightarrow 301 Numerical Solution of Algebraic Equations; 303 Numerical Solution of Ordinary Differential Equations; [3,4]). A method for estimating arithmetic \dagger accumulation errors for operations involving finite numbers of digits has been systematized (\rightarrow 138 Error Analysis; [5]).

It is not unusual nowadays for linear equations with 10,000 or more unknowns to be solved. As new computing systems, such as the virtual memory system and the vector operation system, come into existence, new algorithms are examined; a numerical method that is optimal for today's technology may well be suboptimal for the next generation of computers. General-purpose program packages of linear problems, including eigenvalue problems, have been developed (\rightarrow 298

Numerical Computation of Eigenvalues; [6]).

Partial differential equations seem to have become more familiar because of the visualization of their numerical solutions in graphical computer outputs. In [7], which appeared much earlier than computers, partial difference equations for the fundamental linear problems in mathematical physics were discussed with a suggested variational treatment (\rightarrow 304 Numerical Solution of Partial Differential Equations; [8]). The \dagger finite element method, which started as a calculation technique in structural mechanics and is based on the \dagger calculus of variations, is widely accepted as an efficient approximation method for partial differential equations [9, 10]. The term \dagger simulation is used often to describe procedures in which partial differential equations describing time-dependent phenomena are discretized; the resulting difference system can be solved for long periods of time [11].

Numerical analysis has heretofore long been considered to be the only numerical method (for error analysis in particular), and has been carried out mainly by means of the discretization of equations. Nowadays, however, **mathematical modeling**, taking into account both the phenomena to be described and the capabilities of the computers to be used, has become an important numerical method.

301 (XV.5) Numerical Solution of Algebraic Equations

A. General Remarks

Methods for finding roots of an equation $f(x)=0$ (where $f(x)$ is not necessarily a polynomial, but is assumed to be a function with some regularity) by numerical calculation can in general be divided into the following two types: (i) The first has as its goal the finding of good approximate values of the roots; examples are the Bernoulli method (Section J) and the Graeffe method (Section N). (ii) The second improves the accuracy of estimates of the roots; an example is the Newton-Raphson method (Section D). The methods belonging to (i) and (ii) can be used separately. However, in (i) convergence of the approximations may be excessively slow when a pair of nearly equal roots is present, and the size of numbers involved in the calculation may grow exponentially as we proceed through the iterations. In (ii) convergence of the approximate values is not assured unless the initial approximate value is suitably chosen. Accordingly, when an electronic computer is utilized, it is advisable to combine both types of method. Because of the development of computers, solutions with global convergence have become important [1, 2, 15, 17, 21].

B. Successive Substitutions

When an equation $f(x)=0$ is transformed into $x=F(x)$ and the roots are obtained by iterative calculation of $x_{i+1}=F(x_i)$ ($i=0, 1, 2, \dots$), sufficient conditions for its convergence are as follows: Let one of the roots of the equation be α . Then $x_{i+1}-\alpha=F(x_i)-\alpha$, and therefore $(x_{i+1}-\alpha)/(x_i-\alpha)=F'(\xi)$ ($x_i < \xi < \alpha$ or $x_i > \xi > \alpha$). Accordingly, α converges monotonically if $0 < F'(\xi) < 1$, while it converges with oscillation if $0 > F'(\xi) > -1$. If $|F'(\xi)| > 1$ and $F^{-1}(x)$ denotes the inverse function of $F(x)$, the iteration $x_{i+1}=F^{-1}(x_i)$ converges. To define the speed of convergence by iterative processes the following notion of order is utilized: When $\lim_{i \rightarrow \infty} x_i = \alpha$, the speed of convergence of the sequence $\{x_i\}$ is said to be of the k th order if $\lim_{i \rightarrow \infty} (x_{i+1} - \alpha)/(x_i - \alpha)^k = c \neq 0$. Necessary and sufficient

conditions for the speed of convergence of $\{x_i\}$ to be of the k th order are $\alpha = F(\alpha)$, $F'(\alpha) = F''(\alpha) = \dots = F^{(k-1)}(\alpha) = 0$, $F^{(k)}(\alpha) \neq 0$.

The main iterative processes used in numerical calculation are described in the following sections.

C. Regula Falsi

Regula falsi (or the **method of false position**) is a process of obtaining the real root α of an equation $f(x)=0$ by approaching the root from both sides. The calculation procedure is as follows: Assume that $f(x_p) > 0$ and $f(x_q) < 0$, where x_p and x_q are approximate values of α such that α lies between them. A new approximate value \bar{x} is then obtained from $\bar{x} = (x_q f(x_p) - x_p f(x_q)) / (f(x_p) - f(x_q))$. If $f(\bar{x}) > 0$, then $\bar{x} \rightarrow x_p$, and if $f(\bar{x}) < 0$, then $\bar{x} \rightarrow x_q$, and the procedure is repeated (the symbol \rightarrow means replacement). The conditions and speed of convergence of regula falsi are as follows: Let $F(x) = (x_q f(x) - x f(x_q)) / (f(x) - f(x_q))$; then $F'(\alpha) = (f(x_q) + (\alpha - x_q)f''(\alpha)) / f(x_q)$. If f' and f'' exist and are continuous near α , then $f(x_q) = f(\alpha) + (x_q - \alpha)f'(\alpha) + (1/2)(x_q - \alpha)^2 f''(\xi)$, where $\alpha > \xi > x_q$ or $\alpha < \xi < x_q$. Accordingly, assume that $F'(\alpha) = (1/2)(x_q - \alpha)^2 f''(\xi) / f(x_q) \neq 0$. Then $|F'(x)| < 1$ can be satisfied if x and x_q are near α . Therefore, if the initial value is appropriate, the convergence is of the first order. In regula falsi, only calculation of $f(x)$ is necessary, while that of $f'(x)$ is unnecessary. Furthermore, if $f(x)=0$ has nearby real roots, i.e., α, β, \dots close to each other and $f'(x)$ small near the roots, there can be no mistake such as the neighboring root β being obtained in the process of finding the root α by this method. This method belongs to the inverse linear interpolation method. This kind of inverse interpolation includes Muller's method [3], which uses † Lagrange's interpolation formula, the Torii-Miyakoda method [4], which uses † Hermite's interpolation formula, and Whittaker's method [5], which uses † Stirling's interpolation formula. These methods converge more rapidly but have more complicated formulas than inverse linear interpolation. The **Sturm method** (in which the interval where the roots exist is narrowed by † Sturm's theorem) and the **Horner method** (which obtains the decimal part digit by digit), both used to obtain the real roots of a high-order algebraic equation $f(x)=0$, are also of this type.

D. The Newton-Raphson Method

In obtaining the real roots of an equation $f(x)=0$, the **Newton-Raphson method** (or the **New-**

ton iterative process), which converges rapidly, is used when $f'(x) \neq 0$ is computable. Let x_i be a sufficiently close i th approximation of the root α ; then $x_{i+1} = x_i - f(x_i)/f'(x_i)$ is closer than x_i to the true solution. The process is repeated until $|x_{i+1} - x_i|$ is small enough. Conditions and the speed of convergence are as follows [6, 7]: Let $F(x) = x - f(x)/f'(x)$; then $F'(x) = f(x)f''(x)/(f'(x))^2$ and $F'(\alpha) = 0$. Accordingly, $F''(\alpha) \neq 0$ if $f'(\alpha) \neq 0$ and $f''(\alpha) \neq 0$, and the convergence is of the second order if it is possible to determine an appropriate approximate value x_i that is close to α and satisfies $|F'(x_i)| < 1$. In particular, if $f(x_0)f'(x_0) \neq 0$, $h_0 = -f(x_0)/f'(x_0)$, $|f''(x)| \leq M$, and $|f'(x_0)| \geq 2|h_0|M$, then every Newton approximation x_i starting with x_0 is contained in the interval $I = [x_1 - |h_0|, x_1 + |h_0|]$, the equation has only one root α in I , and $x_i \rightarrow \alpha$. Besides,

$$|\alpha - x_{i+1}| \leq M|x_i - x_{i-1}|^2/2|f'(x_i)|, \quad i = 1, 2, \dots$$

With regard to convergence and evaluation of the error, including roundoff error in practical computations, M. Urabe's studies should be consulted [8, 9]. In general, the convergence is of the third order in the Newton-Raphson method, which uses not only $f'(x)$ but also $f''(x)$ [10].

When $f'(x) = 0$, we must assume $f''(x) \neq 0$ and use the value $f''(x)$. With regard to this case, the study by S. Hitotumatu should be consulted [11]. In addition, W. Kizner (*SIAM J. Appl. Math.*, 12 (1964)) reported an iterative process in which the convergence is of the fifth order without using any derived function higher in order than $f''(x)$. The essential part of his method lies in a numerical integration of the integral part by the †Runge-Kutta formula, based on the fact that if x_1 is the first approximate value of a root \bar{x} of $f(x) = 0$, then

$$\bar{x} = \int_{f(x_1)}^0 \frac{dx}{df} df + x_1.$$

There may be several iterative processes for solving $f(x) = 0$, even if the order k of the convergence is fixed. For example, in obtaining the positive root of $f(x) = x^2 - a = 0$ ($a > 0$), i.e., the square root $\alpha = a^{1/2}$, both iterative processes $x_{i+1} = (x_i + a/x_i)/2$ and $x_{i+1} = 2x_i^3/(3x_i^2 - a)$ give convergence of the second order. In obtaining the real root of $f(x) = x^3 - a = 0$, i.e., the cube root $\alpha = a^{1/3}$, $x_{i+1} = x_i + (a/x_i^2 - x_i)/3$ converges of the second order, while $x_{i+1} = x_i/2 + (a + a/2)/(2x_i^2 + a/x_i)$ converges of the third order.

The Newton-Raphson method is applicable also to holomorphic functions of complex variables.

Take simultaneous equations of two variables, $f(x, y) = 0$ and $g(x, y) = 0$. If it is possible to transform the equations into $x = \varphi(x, y)$ and

$y = \psi(x, y)$, and if $|\partial\varphi/\partial x| + |\partial\psi/\partial x| < 1$, $|\partial\varphi/\partial y| + |\partial\psi/\partial y| < 1$, then the iterative processes $x_{i+1} = \varphi(x_i, y_i)$ and $y_{i+1} = \psi(x_i, y_i)$ are applicable. In the Newton-Raphson method, let the corrections to the i th approximate values x_i and y_i be Δx_i and Δy_i , and solve

$$f_x(x_i, y_i)\Delta x_i + f_y(x_i, y_i)\Delta y_i = -f(x_i, y_i),$$

$$g_x(x_i, y_i)\Delta x_i + g_y(x_i, y_i)\Delta y_i = -g(x_i, y_i).$$

Then we can take $x_{i+1} = x_i + \Delta x_i$ and $y_{i+1} = y_i + \Delta y_i$ as the next approximate values. This process is repeated until both $|\Delta x_i|$ and $|\Delta y_i|$ are sufficiently small. More generally, the Newton-Raphson method for solving a system of n nonlinear equations $f_i(x_1, \dots, x_n) = 0$, $i = 1, 2, \dots, n$, is defined by

$$x^{(k+1)} = x^{(k)} - J(x^{(k)})^{-1}F(x^{(k)}), \quad k = 0, 1, 2, \dots,$$

where $x^{(k)} = (x_1^{(k)}, \dots, x_n^{(k)})^t$, $F(x) = (f_1(x_1, \dots, x_n), \dots, f_n(x_1, \dots, x_n))^t$, $J(x) = (\partial f_i(x_1, \dots, x_n)/\partial x_j)$ (the †Jacobian matrix of F), and where $x^{(0)}$ is chosen appropriately [23].

E. The Bairstow Method

Corresponding to a pair of complex roots $\alpha \pm i\beta$ of an algebraic equation $f(x) = a_0x^n + a_1x^{n-1} + \dots + a_n = 0$ with real coefficients, there is a real quadratic factor $x^2 + p^*x + q^*$. The **Bairstow method** (or **Hitchcock method**) obtains the coefficients p^* and q^* of this quadratic factor.

To do this, first choose an appropriate quadratic factor $x^2 + px + q$ as a candidate. Then through synthetic division by the quadratic factor, b_j and c_j are computed by means of the formulas

$$b_j = a_j - pb_{j-1} - qb_{j-2}, \quad j = 0, 1, \dots, n,$$

and

$$c_j = b_j - pc_{j-1} - qc_{j-2}, \quad j = 0, 1, \dots, n-1,$$

where

$$b_{-1} = b_{-2} = c_{-1} = c_{-2} = 0.$$

By solving the simultaneous equations

$$c_{n-2}\Delta p + c_{n-3}\Delta q = b_{n-1},$$

$$\bar{c}_{n-1}\Delta p + c_{n-2}\Delta q = b_n,$$

where

$$\bar{c}_{n-1} = c_{n-1} - b_{n-1},$$

the quantities Δp and Δq are obtained. Then taking $\bar{p} = p + \Delta p$, $\bar{q} = q + \Delta q$, we have $x^2 + \bar{p}x + \bar{q}$ as a new candidate. This operation is repeated until Δp and Δq are sufficiently small. Since this method corresponds to the Newton-Raphson method in the case of two variables, and, accordingly, the convergence is of the

second order, a choice of suitable initial values of p and q leads to rapid convergence. The key to this method lies in choosing p and q so that $R_1(p, q) = 0$ and $R_2(p, q) = 0$, where R_1 and R_2 are such that $R_1x + R_2$ is the remainder of $f(x)$ divided by the trial quadratic factor $x^2 + px + q$. This method was generalized by A. A. Grau (*SIAM J. Appl. Math.*, 11 (1963)). Namely, when $f(x) = (x^2 + px + q)g(x) + r(x)$ with $r(x) = r_1x^{k+1} + r_2x^k$, the functions r_1 and r_2 can be used instead of R_1 and R_2 . The process corresponds to the Bairstow method when $k = 0$, and to the McAuley method (*SIAM J. Appl. Math.*, 10 (1962)) when $k = n - 2$.

F. The Durand-Kerner Method

The **Durand-Kerner (DK) method** [12] for solving an algebraic equation $f(z) = z^n + a_1z^{n-1} + \dots + a_n = 0$ ($a_n \neq 0$) with complex coefficients is an iterative method defined by

$$z_i^{(k+1)} = z_i^{(k)} - \frac{f(z_i^{(k)})}{\prod_{j=1, j \neq i}^n (z_i^{(k)} - z_j^{(k)})}, \quad i = 1, 2, \dots, n, \quad k = 0, 1, 2, \dots \quad (1)$$

A feature of this method is that it can determine simultaneously all the roots of $f(z) = 0$. Let $\varphi_m(z_1, \dots, z_n)$, $m = 1, 2, \dots, n$, be the m th elementary symmetric functions with respect to z_1, \dots, z_n :

$$\varphi_m(z_1, \dots, z_n) = \sum_{i_1 < i_2 < \dots < i_m} z_{i_1} z_{i_2} \dots z_{i_m}.$$

Set $f_m(z) = (-1)^m \varphi_m(z_1, \dots, z_n) - a_m$. Then $\alpha = (\alpha_1, \dots, \alpha_n)^t$, a set of the roots of $f(z) = 0$, is a solution of a system of the n equations $f_m(z) = 0$, $m = 1, 2, \dots, n$. I. O. Kerner [12] showed that the DK method is the Newton-Raphson method applied to the system of nonlinear equations $f_m(z) = 0$, $m = 1, 2, \dots, n$. Therefore the speed of convergence of (1) is of the second order, provided that it converges. The initial values $z_1^{(0)}, \dots, z_n^{(0)}$ for the DK method are usually chosen as follows: Let $g(z) = f(z - a_1/n) = z^n + c_2z^{n-2} + \dots + c_n$ and $h(z) = z^n - |c_2|z^{n-2} - \dots - |c_n|$. If $(c_2, \dots, c_n) \neq (0, \dots, 0)$ ($n \geq 2$), then it can be shown that $h(z) = 0$ has exactly one positive root r , and all the roots of $f(z) = 0$ lie in the disk $|z + a_1/n| \leq r$. Now, with a positive $r_0 \geq r$ and $\theta = \pi/(2n)$, put

$$z_i^{(0)} = -\frac{a_1}{n} + r_0 \exp \left[\left(\frac{2(i-1)\pi}{n} + \theta \right) \sqrt{-1} \right], \quad i = 1, 2, \dots, n. \quad (2)$$

Such a choice was proposed by O. Aberth [13]. Hence the process (1) together with (2) can be called the **Durand-Kerner-Aberth (DKA) method**. It is shown for the DKA

method that, if r_0 is large enough, then

$$z_i^{(k)} + \frac{a_1}{n} = \left(1 - \frac{1}{n} \right)^k \left(z_i^{(0)} + \frac{a_1}{n} \right), \quad i = 1, 2, \dots, n,$$

hold nearly for the first several steps. Thus the DKA method has a certain kind of global convergence property that renders it one of the most powerful methods for solving algebraic equations.

A variant of the Durand-Kerner method is the Ehrlich-Aberth method [13, 14]; it is defined for $i = 1, 2, \dots, n$, $k = 0, 1, 2, \dots$ by

$$z_i^{(k+1)} = z_i^{(k)} - \frac{f(z_i^{(k)})}{f'(z_i^{(k)}) - f(z_i^{(k)}) \sum_{j=1, j \neq i}^n 1/(z_i^{(k)} - z_j^{(k)})}.$$

The speed of convergence of this method is of the third order. Further variants of the Durand-Kerner and the Ehrlich-Aberth methods have been proposed by M. Iri et al. [15] and A. W. M. Nourain [16].

G. The Dejon-Nickel Method

Let $f(z)$ be a polynomial of degree n with complex coefficients, and take z_0 such that $f(z_0) \neq 0$. Then we can write

$$f(z_0 + h) = f(z_0) \{ 1 + b_1 h^i + b_{i+1} h^{i+1} + \dots + b_n h^n \} \quad (b_i \neq 0) \\ = f(z_0) \{ 1 + b_i h^i (1 + \theta) \}, \quad \theta = o(h).$$

Now, choose h sufficiently small so that $|b_i h^i| < 1$, $|\theta| < 1$, and $\arg(b_i h^i) = \pi$. Then $|1 + b_i h^i| = 1 - |b_i h^i|$ and $|b_i h^i \theta| < |b_i h^i|$ so that $|f(z_0 + h)| \leq |f(z_0)| \{ |1 + b_i h^i| + |b_i h^i \theta| \} < |f(z_0)|$. Hence, if z_0 is chosen so that $\min |f(z)| = |f(z_0)|$, then we must have $f(z_0) = 0$. This is the outline of Cauchy's existence proof for the roots of algebraic equations. The **Dejon-Nickel method** [17] is a method in which h is chosen as follows:

$$h = (-1/b_k)^{1/k},$$

where

$$\min \{ |1/b_j|^{1/j} \mid b_j \neq 0, i \leq j \leq n \} = |1/b_k|^{1/k} \quad (=r, \text{ say}).$$

If several such k exist, take the smallest one.

The branch of the multivalued function $(-1/b_k)^{1/k}$ is chosen such that $z^{1/k}$ is positive for z positive. If $|f(z_0 + h)| \leq (1 - \varepsilon)|f(z_0)|$ with a preassigned constant ε such that $0 < \varepsilon < 1$, then put $z_1 = z_0 + h$. If the inequality does not hold, then for each integer $m \geq 1$ choose the smallest integer $l = l(m)$ such that $\max \{ |b_j| (r/2^m)^j \mid i \leq j \leq n \} = |b_l| (r/2^m)^l$, and put $\tilde{z}_m = z_0 + (r/2^m) (-|b_l|/b_l)^{1/l}$. Find the smallest integer $m \geq 1$ such that $|f(z_0)| \leq (1 - 2^{-1} (r/2^m)^l |b_l|) |f(z_0)|$, and put

$z_1 = \tilde{z}_m$. By continuing this process, a sequence $\{z_j\}$ is constructed such that $|f(z_0)| > |f(z_1)| > |f(z_2)| > \dots$. It converges toward some root of the equation $f(z) = 0$. S. Hirano has proposed a similar method.

H. Methods for Finding Good First Estimates of Roots

Some of the principal methods for obtaining good first approximate values of the roots are given in the following sections I–N.

I. Matrix Methods

The problem of solving an algebraic equation $f(z) = z^n + a_1 z^{n-1} + \dots + a_n = 0$ with complex coefficients is equivalent to that of finding the eigenvalues of the **companion matrix**

$$A = \begin{bmatrix} -a_1 & -a_2 & -a_3 & \dots & -a_{n-1} & -a_n \\ 1 & 0 & 0 & \dots & 0 & 0 \\ 0 & 1 & 0 & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & 1 & 0 \end{bmatrix}.$$

Therefore numerical methods for solving the eigenvalue problems for nonsymmetric matrices are applicable (\rightarrow 298 Numerical Computation of Eigenvalues). However, it should be remarked that this might be inefficient because most of the elements of the matrix A are zero [18].

J. The Bernoulli Method

In the **Bernoulli method** the iterative formulas $S_1 = -a_1$, $S_k = -(a_1 S_{k-1} + a_2 S_{k-2} + \dots + a_{k-1} S_1 + k a_k)$ ($k = 2, 3, \dots, n$), $S_k = -a_1 S_{k-1} - a_2 S_{k-2} - \dots - a_n S_{k-n}$ ($k = n+1, n+2, \dots$) are repeatedly applied to an algebraic equation $f(x) = x^n + a_1 x^{n-1} + a_2 x^{n-2} + \dots + a_n = 0$. When the roots of $f(x) = 0$ are $\alpha_1, \alpha_2, \dots, \alpha_n$ ($|\alpha_1| \geq |\alpha_2| \geq \dots \geq |\alpha_n|$), $S_k/S_{k-1} \rightarrow \alpha_1$ if α_1 is a real and simple root and $|\alpha_1| > |\alpha_2|$. When α_1, α_2 are complex roots, we put $\alpha_1 = R e^{i\theta}$, $\alpha_2 = R e^{-i\theta}$. If $|\alpha_3| < R$, then we have

$$\frac{S_k^2 - S_{k+1} S_{k-1}}{S_{k-1}^2 - S_k S_{k-2}} \rightarrow R^2,$$

$$\frac{S_k S_{k-1} - S_{k+1} S_{k-2}}{S_{k-1}^2 - S_k S_{k-2}} \rightarrow 2R \cos \theta,$$

and hence the two roots of $x^2 - (2R \cos \theta)x + R^2 = 0$ are α_1 and α_2 . S_k is the sum of the k th powers of the n roots of the equation, $\alpha_1, \alpha_2, \dots, \alpha_n$. C. Lanczos used $x f'(x)/f(x) = n + S_1/x + S_2/x^2 + \dots + S_k/x^k + \dots$ to compute S_k [10, pp. 26–30]. Let the eigenvalues of the companion matrix A be $\lambda_1, \lambda_2, \dots, \lambda_n$ ($|\lambda_1| \geq |\lambda_2| \geq$

$\dots \geq |\lambda_n|$). Then the Bernoulli method is the same as the \dagger power method for obtaining the maximum characteristic value λ_1 (\rightarrow 298 Numerical Computation of Eigenvalues C).

K. The Lehmer Method

The **Lehmer method** [9] is a general method for finding the n roots of an algebraic equation with complex coefficients

$$f(z) = a_0 + a_1 z + a_2 z^2 + \dots + a_n z^n = 0$$

in the complex plane by repeating the following procedure: First, draw a circle whose center is at the origin and whose radius is $R = r 2^{-\theta}$, where r is an arbitrary given number and θ an arbitrary given integer. Then, utilizing the Lehmer theorem, observe whether a root α of $f(z) = 0$ lies inside the circle. If there is no such root, replace R with $2R$, whereas if such a root exists, replace R with $R/2$. Continue this process until an R for which a root α exists within the annulus $R < |z| < 2R$ is obtained.

Second, draw circles with the centers $\beta_k = (5R/3) \exp(i 2\pi k/8)$ ($k = 0, 1, \dots, 7$) and common radius $\mu = (5R/3)/2$ and cover the annulus obtained by the first step. Then find out which of the circles has the root α in its interior. If α is in the interior of the circle for $k = j$, the origin is shifted to β_j and the operation is started again from the first step. If R_1 satisfying $R_1 < |z - \beta_j| < 2R_1$ is obtained by the first step, we have $R_1 \leq (5/12)R$. Therefore, when the first step is repeated N times, the root α is confined in a small circle whose radius is smaller than $2(5/12)^N R$. Then the center β of this small circle gives a good approximate value of α .

L. The Downhill Method

The downhill method is a method for obtaining the extreme values of a function of many variables. It is also applicable in obtaining approximate solutions of a system of equations. Let us consider the **downhill method** in the case of two variables. The problem of obtaining the real roots of simultaneous equations $f(x, y) = 0$ and $g(x, y) = 0$ can be reduced to the problem of obtaining the coordinates (α, β) which give the extreme value 0 of $\Phi(x, y)$, where $\Phi(x, y) = f^2 + g^2$. The values of $\Phi(x, y)$ are calculated at 3^2 points obtained by the combination of $x = x_1, x_1 \pm h; y = y_1, y_1 \pm h$, where (x_1, y_1) are arbitrary approximate values of (α, β) constituting the centers of those sets of points, and h is the given step size. Utilizing the values of the function at the 3^2 points,

$\Phi(x, y)$ is approximated by a quadratic surface

$$b_0 + b_1x + b_2y + b_{11}(3x^2 - 2) + b_{22}(3y^2 - 2) + b_{12}xy.$$

The values of $b_0, b_1, b_2, b_{11}, b_{22}, b_{12}$ are calculated by the †method of least squares, and the center (x_1^*, y_1^*) of the approximate quadratic surface is obtained. Then the first approximations x_1 and y_1 are replaced by the second approximations $x_1 + x_1^*$ and $y_1 + y_1^*$. This process is repeated while the step size h is made appropriately smaller. This method is an improvement on the method of successive experimental planning used by G. E. P. Box and K. B. Wilson (1954) to obtain optimum conditions in the exploration of response curved surfaces.

By using another minimization technique, J. A. Grant and G. D. Hitchins [21] gave an ever-convergent algorithm for determining initial approximations to the roots of algebraic equations with real coefficients. The practical implementation of this method is given in J. A. Grant and G. D. Hitchins (*Comput. J.*, 18 (1975)).

M. Continuation Methods

Let $F(x) = (f_1(x), \dots, f_n(x))^t = 0$ ($x = (x_1, \dots, x_n)^t$) be a system of n equations. Suppose that no reasonable approximation for a solution exists. Then, take arbitrary $x^{(0)}$ and define a one-parameter family of equations

$$H(x, t) \equiv F(x) - (1-t)F(x^{(0)}) = 0, \quad 0 \leq t \leq 1. \quad (3)$$

Suppose that for each t the equation has a solution $x(t)$ which depends continuously on t . Observe then that $x(0) = x^{(0)}$ and $x(1)$ is a solution for the equation $F(x) = 0$. Partition the interval $[0, 1]$ by the points $0 = t_0 < t_1 < \dots < t_N = 1$. First, solve $H(x, t_1) = 0$ by some iterative method using $x^{(0)}$ as a first approximation. Let $x^{(1)}$ be a solution thus obtained. Next, solve $H(x, t_2) = 0$ by some iterative method using $x^{(1)}$ as a first approximation, and so on. Finally, solve $H(x, t_N) = 0$ by some iterative method which uses $x^{(N-1)}$ as a first approximation. Then $x^{(N)}$, a solution thus obtained, can be used as a first approximation in an iterative method applied to the equation $F(x) = 0$. This method is called a **continuation method** [22–24].

As another approach, differentiate (3) with respect to t . Then $J(x(t))x'(t) + F(x^{(0)}) = 0$, where $J(x(t))$ is the Jacobian matrix of F , evaluated at $x = x(t)$. Hence $x(t)$ is the solution of the system of ordinary differential equations $x'(t) = -J(x(t))^{-1}F(x^{(0)})$, $0 \leq t \leq 1$,

subject to the initial condition $x(0) = x^{(0)}$, provided that $J(x(t))$ is nonsingular. Therefore numerical solution at $t = 1$ gives a good approximation for a solution of $F(x) = 0$. This is called **Daivenko's method of differentiation with respect to a parameter**. These methods can be used to find initial approximations of the Durand-Kerner and the Ehrlich-Aberth methods. They are also applicable to a single algebraic equation $f(x) = 0$, which is the special case $n = 1$.

N. Other Methods

To obtain the first approximate values of the roots of an algebraic equation, the Graeffe method has been used, in which the roots of the equation are separated by successively forming an equation whose roots are the squares of the roots of the preceding equation. In computer calculations, however, the other methods described in previous sections are more convenient than the Graeffe method.

The **Lanczos method** [10] is a method in which $g(x)$, an approximate function of $f(x)$, is obtained by the process of approximating functions, and the roots of $g(x) = 0$ are taken as approximate values of the roots of $f(x) = 0$. The Garside-Jarratt-Mack method [25] is a modification of the Lanczos method and approximates $f(x)/f'(x)$ by a rational function $g(x) = (x-a)/(b+cx)$.

O. Error Bounds for Computed Solutions

Let z_1, \dots, z_n be computed solutions of an algebraic equation $f(z) = 0$ which were obtained by some method. If z_1, \dots, z_n are distinct, then the following result due to B. T. Smith [26] is quite useful for estimating the errors of z_i : Let

$$\Gamma_i: |z - z_i| \leq \gamma_i \equiv \frac{n|f(z_i)|}{\prod_{j=1, j \neq i}^n |z_i - z_j|}.$$

Then the union of the disks Γ_i contains all the roots $\alpha_1, \dots, \alpha_n$ of $f(z) = 0$. Any connected component of $\bigcup_{i=1}^n \Gamma_i$, which consists of just m disks Γ_i , contains exactly m roots of $f(z) = 0$. Hence if $\Gamma_i \cap \Gamma_j = \emptyset$ for every $j \neq i$, then $|\alpha_i - z_i| \leq \gamma_i$. Smith obtained a more general result for the case where z_1, \dots, z_n are not necessarily distinct.

302 (XV.4) Numerical Solution of Linear Equations

A. Condition of Linear Systems

The solution of the system of linear algebraic equations

$$\sum_{j=1}^n a_{ij}x_j = b_i; \quad i = 1, \dots, n, \quad a_{ij}, b_i \text{ real}, \quad (1)$$

which may be written in the matrix form

$$Ax = b; \quad A = (a_{ij}), \quad x = (x_i), \quad b = (b_i), \quad (1')$$

is expressed as quotients of determinants by Cramer's rule. In practice, however, this form of the solution is of little value for numerical computation, because the direct evaluation of the determinants involves $(n+1)!(n-1)$ multiplications which, even for a moderate-sized system, amount to a prohibitive number of arithmetic operations to be executed, even with modern high-speed computers; besides, it requires high-precision calculation. There are a variety of practical methods of solving efficiently the system (1) with finite-precision calculation. These numerical methods are generally divided into two classes: direct methods and iterative methods.

Whatever method is used, inherent difficulties are encountered when the solution of the system is unstable. The instability is usually measured by the **condition number** of the coefficient matrix, which is defined by

$$\text{cond } A = \sigma_1 / \sigma_n \quad (\|A\| \|A^{-1}\| \geq 1), \quad (2)$$

where the σ_i ($\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n \geq 0$) are the non-negative square roots of the eigenvalues of $A^t A$ (called the **singular values** of A), $\|A\| = \max \{\|Ax\|/\|x\| : x \neq 0\}$, and $\|x\| = \sqrt{x^t x}$. This definition is valid also for an $m \times n$ matrix A ($m \geq n$). The condition number $\text{cond } A$ satisfies

$$\frac{\|\delta x\|}{\|x\|} \leq \frac{\text{cond } A}{1 - \frac{\|\delta A\|}{\|A\|} \text{cond } A} \left(\frac{\|\delta A\|}{\|A\|} + \frac{\|\delta b\|}{\|b\|} \right),$$

where $Ax = b$, $(A + \delta A)(x + \delta x) = b + \delta b$, and $\|\delta A\| \|A^{-1}\| < 1$. As the condition number increases, solution processes become more susceptible to errors. If $\text{cond } A$ is large, the system is called **ill-conditioned**.

B. Direct Methods

A direct method is one that yields an exact solution in a finite number of arithmetic operations if they are performed without roundoff error. Among the existing direct methods, the one known as **Gaussian elimination** with pivoting, which is based on systematic elimination of unknowns of the equation (1), is found to be the best with respect to time or accuracy. Its dependability was re-established by means of **backward error analysis** (\rightarrow 138 Error Analysis; [1–3]). The method generates successive vectors $b^{(k)} = (b_i^k)$ and matrices $A^{(k)} = (a_{ij}^k)$, typically of the form

$$A^{(2)} = \begin{pmatrix} * & * & * & * & * \\ 0 & * & * & * & * \\ 0 & 0 & * & * & * \\ 0 & 0 & * & * & * \\ 0 & 0 & * & * & * \end{pmatrix}$$

when $n = 5$ and $k = 2$. At the k th stage, a pivotal element $a_{ij}^{k-1} \neq 0$ ($i, j \geq k$) is chosen in one way or another. Then the i th and k th rows and the j th and k th columns of $A^{(k-1)}$ are interchanged so that a_{ij}^{k-1} becomes a_{kk}^k . The i th and k th elements of $b^{(k-1)}$ are also interchanged. The **pivot** a_{kk}^k is then used to eliminate all the nonzero entries in its column below the diagonal as follows:

$$a_{ij}^k = a_{ij}^{k-1}, \quad i = 1, \dots, k, \quad j = 1, \dots, n;$$

$$b_i^k = b_i^{k-1}, \quad i = 1, \dots, k;$$

$$a_{ij}^k = a_{ij}^{k-1} - (a_{ik}^{k-1}/a_{kk}^k) a_{kj}^k,$$

$$i = k + 1, \dots, n, \quad j = k, \dots, n;$$

$$b_i^k = b_i^{k-1} - (a_{ik}^{k-1}/a_{kk}^k) b_k^k, \quad i = k + 1, \dots, n.$$

Starting with $A^{(0)} = A$ and $b^{(0)} = b$, a system of linear equations with an upper-triangular coefficient matrix,

$$A^{(n-1)} x^* = b^{(n-1)},$$

is produced at the stage $k = n - 1$, where x^* is a permutation of x , caused by interchanging columns. This part of the process is called **forward elimination**. If $a_{ij}^{k-1} = 0$ for all $i, j \geq k$ at some stage, then A is a singular matrix of rank $k - 1$ and the system (1) admits infinitely many solutions if $b_i^{k-1} = 0$ for $i = k, \dots, n$, and no solution otherwise. If this is not the case, A is a nonsingular matrix with $\det A = a_{11}^{n-1} a_{22}^{n-1} \dots a_{nn}^{n-1}$, and the solution of (1) is given by

$$x_i^* = \left(b_i^{n-1} - \sum_{k=i+1}^n a_{ik}^{n-1} x_k^* \right) / a_{ii}^{n-1}$$

for $i = n, n - 1, \dots, 1$, which is called **back substitution**. Taking the pivot to be an element of the largest absolute value among column elements a_{ik}^{k-1} ($i \geq k$) at each stage is called the **partial pivoting** strategy. In **complete pivoting**, the pivot is taken to be an element of the largest absolute value among a_{ij}^{k-1} ($i, j \geq k$).

These pivotings are introduced to prevent loss of accuracy due to rapid growth of elements of successive $A^{(k)}$. Although a smaller bound for the growth factor is obtained for complete pivoting, in practice partial pivoting appears to be entirely adequate.

If rows or columns are not interchanged in the process, forward elimination effectively produces a factorization of A into the product of a lower triangular matrix L and an upper triangular matrix U , i.e.,

$$A = LU, \quad (3)$$

where L has unit diagonal elements and $U = A^{(n-1)}$. This factorization is computed directly by the **Doolittle method** without calculating the intermediate $A^{(k)}$. The **Crout method** also produces a similar factorization (3) in which U has unit diagonal elements. The **Cholesky method** determines a similar factorization (3) of a positive definite matrix A , in which $U = L^t$. Once the **triangular factorizations** (3) are formed, the solution of the system (1) is determined by solving the two triangular systems $Ly = b$ and $Ux = y$ successively.

The number of multiplicative operations required for these factorizations are about $n^3/3$ for forward elimination, Doolittle's method, and Crout's method, and about $n^3/6$ for Cholesky's method. The solution of each triangular system requires about $n^2/2$ multiplicative operations. Special properties of A , such as a banded structure, can be exploited to reduce the number of operations and memory requirements considerably [4]. **Gauss-Jordan elimination** is similar to Gaussian elimina-

tion, but the elements above the diagonal are also eliminated to dispense with back substitution. However, it requires about $n^3/2$ multiplications. Modern computers can easily handle problems of size $n = 100$ by these direct methods.

C. Iterative Methods

An iterative method is a dynamical process that generates a sequence of approximations $\{x^k\}$ converging to the exact solution. At each step of the iteration, an improved approximation is obtained from the previous ones. The accuracy of the solution depends on the number of iterations performed. Most iterative methods retain the coefficient matrix in its original form throughout the process and hence have the advantage of requiring minimal memory. They are suitable for solving large **sparse** systems arising in finite-dimensional approximations to \dagger partial differential equations, where A is sparse if most of its elements are zero.

Linear stationary iterative processes are the most frequently used iterative methods. A method in this class is written in the form

$$x^k = x^{k-1} + R(b - Ax^{k-1}), \quad k = 1, 2, \dots, \quad (4)$$

where R is chosen to approximate the inverse of A . Usually, R and $b - Ax^{k-1}$ are not expressed explicitly in the actual algorithms. If the \dagger spectral radius of the **iteration matrix** $I - RA$ is less than one, the method converges to the solution for an arbitrary initial approximation x^0 [5]. The key matrix R can be chosen quite freely as long as this condition is satisfied. In the **Richardson method**, $R = \alpha A^{-1}$, $0 < \alpha < 2/\|A\|^2$. $R = (A + E)^{-1}$ is the usual choice, in which E is a perturbing matrix that makes $A + E$ easily invertible. In the **Gauss-Seidel method** and the **Jacobi method**, R is chosen to be the inverse of the lower triangular and the diagonal submatrices of A , respectively, i.e., $R = (L + D)^{-1}$ and $R = D^{-1}$, where $L = (a_{ij})$ ($i > j$) and $D = (a_{ii})$.

Direct methods can be combined with the iterative method (4) to obtain an approximate inverse R . In the course of factorization by a direct method, an artificial perturbation E is introduced to produce an **incomplete factorization**,

$$\tilde{L}\tilde{U} = A + E, \quad (5)$$

so that \tilde{L} and \tilde{U} are of low \dagger complexity of computation. A combined method is then constructed by putting $R = \tilde{U}^{-1}\tilde{L}^{-1}$. Even if E is not added intentionally, each of the direct methods actually produces an incomplete factorization (5), in which E is a matrix of

small elements accounting for the effect of roundoff errors [1–4]. In this case, the combined method is called the **iterative improvement** of the direct method. If applied to a first solution $x^0 = \tilde{U}^{-1}\tilde{L}^{-1}b$, it produces more accurate solution in a few steps with only a modest increase in computation time, when the system is not too ill-conditioned [4]. It is essential, however, that the residual $b - Ax^0$ be computed with higher precision.

Various convergence criteria have been established for a variety of methods [5, 6]. For example, the Gauss-Seidel method is convergent for a symmetric positive definite matrix A . The smaller the spectral radius, the faster the convergence of the method. In general, a larger amount of computation is required in each iteration to get faster convergence. If the spectral radius $\rho(I - RA)$ is close to one, the convergence is slow, and an acceleration of the process is needed. **SOR** (successive over-relaxation) is an accelerated version of the Gauss-Seidel method, in which $R_\omega = (L + \omega^{-1}D)^{-1}$ and the optimum **acceleration parameter** ω ($0 < \omega < 2$) is chosen to minimize $\rho(I - R_\omega A)$ (\rightarrow 304 Numerical Solution of Partial Differential Equations; [6]). There is an adaptive acceleration method [7], which, if applied to a scalar sequence, reduces to Aitken's δ^2 -method.

D. The Conjugate Gradient Method

The **conjugate gradient (CG) method** is a nonlinear stationary iterative method for solving a system with a symmetric positive definite coefficient matrix. The method generates $\{x^k\}$, $\{r^k\}$, and $\{p^k\}$ by means of the formulas

$$\begin{aligned} \alpha_k &= (r_k, r_k)/(p^k, Ap^k), \\ x^{k+1} &= x^k + \alpha_k p^k, \\ r^{k+1} &= b - Ax^{k+1} = r^k - \alpha_k Ap^k, \\ \beta_k &= (r^{k+1}, r^{k+1})/(r^k, r^k), \\ p^{k+1} &= r^{k+1} + \beta_k p^k, \end{aligned} \quad (6)$$

where x^0 is arbitrary and $p^0 = r^0 = b - Ax^0$, $(r, s) = s^T r$.

The CG method shares a feature with the direct method. In theory, $\{x^k\}$ converges to the solution in less than n steps, and the p^i are mutually **conjugate**, i.e., $(p^i)^T Ap^j = 0$ ($i \neq j$). When Hestenes and Stiefel [9] proposed the method in 1952, they created a great sensation because of the method's theoretical elegance. The CG method turned out, however, to be highly sensitive to roundoff errors. In practice, nice theoretical properties, such as finite termination, do not hold in the presence of error. Recently, the CG method has regained its

popularity as an iterative method for solving large sparse systems. The iteration (6) is usually restarted periodically to accelerate the convergence. It may converge in a small number of steps, as it takes advantage of the distribution of eigenvalues of A adaptively. The CG method is most effective when it is used to accelerate linear stationary iterative methods or when it is applied to the **preconditioned** system

$$\tilde{L}^{-1}A(\tilde{L}^{-1})^T y = L^{-1}b, \quad x = (L^{-1})^T y, \quad (7)$$

where \tilde{L} is computed by the incomplete Cholesky factorization $\tilde{L}\tilde{L}^T = A + E$. The matrix $\tilde{L}^{-1}A(\tilde{L}^{-1})^T$ is not to be formed explicitly in the CG method.

E. Linear Least Squares Problem

Let $Ax = b$ be an overdetermined system of linear equations, where A is an $m \times n$ matrix ($m \geq n$). The **linear least squares problem** is to find the x that minimizes the Euclidean norm $\|b - Ax\|$. We assume here that A is of rank n . The most straightforward method for solving the problem is to apply the Cholesky method to the **normal equation**

$$(A^T A)x = A^T b. \quad (8)$$

This may result in ill-conditioning of the system, since $\text{cond } A^T A = (\text{cond } A)^2$. Ill-conditioning can sometimes be avoided by forming the factorization $A = LU$ by Gaussian elimination, where L is an $m \times n$ lower trapezoidal matrix and U is an upper triangular matrix. The least squares solution is then obtained by solving successively the systems $L^T L y = L^T b$ and $Ux = y$.

Another approach to avoiding ill-conditioning is based on orthogonalization. The modified Gram-Schmidt orthogonalization method produces in an effective manner the factorization

$$A = QU, \quad (9)$$

where Q is an $m \times n$ matrix whose columns are a set of orthonormal vectors and U is an upper triangular matrix [10, 11]. The least squares solution is obtained by solving $Ux = Q^T b$. A sequence of **Householder transformations**, $P_k = I - 2w_k w_k^T / \|w_k\|^2$, can produce the factorization

$$P_n P_{n-1} \dots P_2 P_1 A = \begin{pmatrix} U \\ 0 \end{pmatrix}, \quad (10)$$

where U is an $n \times n$ upper triangular matrix [12]. The least squares solution is obtained by solving $Ux = \bar{b}$, where \bar{b} is formed by the first n elements of the vector $P_n P_{n-1} \dots P_2 P_1 b$. A

similar factorization can also be produced by using a sequence of **Givens transformations**, which have the advantage of exploiting the sparseness of A . The matrices U in (9) and (10) are unique and coincide with the transpose L^T of the lower triangular matrix L of the Cholesky factorization, $A^T A = LL^T$, of $A^T A$. The multiplicative operations required for the factorizations (9) and (10) are about mn^2 and $mn^2 - n^3/3$, respectively.

When the rank of the matrix is unknown, we can determine an "effective rank" p of A , based on the **singular value decomposition** (SVD):

$$A = UDV^T,$$

where U and V are orthogonal matrices of dimensions m and n , respectively, and D is an $m \times n$ diagonal matrix whose diagonal elements d_{ii} are the singular values σ_i of A [13]. If singular values smaller than σ_p can be ignored, the approximate least squares solution is given by $\hat{x}^p = V \tilde{D}_p^+ U^T b$, where the i th element \tilde{d}_{ii}^p of the diagonal matrix \tilde{D}_p^+ is σ_i^{-1} if $i \leq p$ and 0 otherwise.

These methods certainly solve the system (1) but generally require more computational work than those based on the triangular factorization. The least squares solution is computed also by applying the CG method (6) to the normal equation (8), in which $A^T A$ is not to be formed explicitly [9]. Iterative methods for solving linear systems with singular and rectangular coefficient matrices are characterized in terms of the range of RA and the null space of AR [15].

Besides the methods discussed here, numerous other methods have been proposed for solving the system (1) [16–18]. Recently, various sparse techniques have been developed for direct methods to control the growth of non-zero entries (**fill-in**) in the process of matrix factorization [19]. In general, direct methods have an advantage over iterative methods; however, their relative computational efficiency varies according to the scale, sparsity, and type of the coefficient matrix and to the available computational devices.

303 (XV.8) Numerical Solution of Ordinary Differential Equations

A. General Remarks

Applications of the numerical solution of *ordinary differential equations include *initial value problems, *boundary value problems,

and *eigenvalue problems. Although solution by an *analog computer is among the numerical methods in the wide sense, we usually mean by “numerical solution” a solution obtained by approximating a problem of infinite degrees of freedom and a continuous variable by one of finite degrees of freedom. The approximation of an arbitrary function by a linear combination of a given finite system of functions is an example (\rightarrow Section I). Successive substitution and power series expansion are also used but have no particular advantages over other methods. Among various methods of approximation, the so-called **difference methods** (or **discrete variable methods**) are the most flexible and have the largest field of application. A difference method reduces a given problem to an approximate problem in which we deal only with a systematically chosen set of discrete values of the variable and with values of the unknown functions at the chosen points. A difference method is usually carried out by a simple iterative computation, so that it is suitable for *digital computers. We confine ourselves almost exclusively to difference methods [1–7].

B. Initial Value Problems

To solve numerically general initial value problems, it suffices to consider the problem of determining numerically the values on an interval $[a, b]$ of m functions $y^i(x)$ ($i = 1, \dots, m$) that satisfy a system of ordinary differential equations of the form $y^{i\prime\prime}(x) = f^i(x, y^1(x), \dots, y^m(x))$ and the initial conditions $y^i(a) = \eta^i$ ($i = 1, \dots, m$), where the f^i are given functions with appropriate smoothness, and a, b , and η^i are given constants. We define the mesh points $x_n = a + nh$ ($n = 0, 1, \dots$), call h the **step size**, and determine numerically the values y_n^i approximating $y^i(x_n)$.

Assuming that the y_n^i were computed with infinite accuracy, i.e., without *roundoff error, we call $e_n^i \equiv y_n^i - y^i(x_n)$ the global **truncation error** (or global **discretization error**), while we call $r_n^i \equiv \tilde{y}_n^i - y_n^i$ the global **roundoff error**, where the \tilde{y}_n^i are the values we actually have by means of finite-accuracy computation. On the other hand, if the assumption holds locally that the solutions at the previous steps are exact, we call the e_n^i and r_n^i the local truncation error (or local discretization error) and the local roundoff error, respectively. To avoid confusion, we denote the local truncation error by t_n^i . The numerical solution must have the property that, for every $x \in [a, b]$, $\lim_{h \rightarrow 0, x_n = x} e_n^i = 0$, which is called the condition of **convergence**. In particular, if $t_n^i = O(h^{p+1})$ ($x_n = x, h \rightarrow 0$, where $O(h^{p+1})$ is Landau's symbol), then p

is called the **order** of the solution process.

We shall show the typical methods of numerical solution, using the abbreviation f_n^i for $f^i(x_n, y_n^i)$.

C. Overall Approximation

If we rewrite the differential equations on the interval $[x_n, x_{n+P}]$ as $y^i(x_{n+q}) - y^i(x_n) = \int_{x_n}^{x_{n+q}} f^i(x, y^j(x)) dx$, $q = 1, \dots, P$, and substitute suitable numerical integration formulas for the integrals on the right-hand side, then we have the **overall approximation formulas**:

$$y_{n+q}^i - y_n^i = h \sum_{r=0}^P c_{qr} f_{n+r}^i, \quad q = 1, \dots, P,$$

from which we can obtain $y_{n+1}^i, \dots, y_{n+P}^i$ when the y_n^i are given. Since f_{n+r}^i contains y_{n+r}^i , these equations are nonlinear in y_{n+q}^i , so that we have to use, for example, the iterative procedure of starting from suitable 0th approximations and adopting as the l th approximations of the y_{n+q}^i values computed from the overall approximation formulas by substituting the $(l-1)$ th approximations for the y_{n+r}^i in the f_{n+r}^i on the right-hand sides. These formulas are often used to determine a set of starting values for a multistep method. The truncation error of the formulas depends on that of the numerical integration formula substituted for the integral. A few examples: $P = 1$, $(c_{10}, c_{11}) = (1/2, 1/2)$ (error $h^3 y^{(3)}(x_n)/12 + O(h^4)$); $P = 2$, $(c_{10}, c_{11}, c_{12}) = (5/12, 8/12, -1/12)$ (error $-h^4 y^{(4)}(x_n) + O(h^5)$), $(c_{20}, c_{21}, c_{22}) = (1/3, 4/3, 1/3)$ (error $h^5 y^{(5)}(x_n) + O(h^6)$); $P = 3$, $(c_{10}, c_{11}, c_{12}, c_{13}) = (9/24, 19/24, -5/24, 1/24)$, $(c_{20}, c_{21}, c_{22}, c_{23}) = (1/3, 4/3, 1/3, 0)$, $(c_{30}, c_{31}, c_{32}, c_{33}) = (3/8, 9/8, 9/8, 3/8)$.

D. Runge-Kutta Methods

By a **general Runge-Kutta method** we mean a method of determining $y_0^i = \eta^i, y_1^i, y_2^i, \dots$ successively by means of a formula $y_{n+1}^i - y_n^i = h\Phi^i(x_n, y_n^j, h)$, where the functions Φ^i are defined in terms of parameters α_r and β_{rs} as $\Phi^i(x, y^j, h) = \sum_{r=0}^P \alpha_r k_r^i$, $k_0^i = f^i(x, y^j)$, $k_r^i = f^i(x + \beta_{r0}h, y^j + h(\sum_{s=1}^P \beta_{rs} k_s^i + h \sum_{s=1}^P \beta_{rs} k_s^j))$ ($r = 1, \dots, P$). A Runge-Kutta method is called **explicit** if $\beta_{rs} = 0$ for $r \leq s$, and **implicit** otherwise. In the latter case, if $\beta_{rs} = 0$ for $r < s$, the method is called **semi-explicit** (or **semi-implicit**). Unless otherwise stated, the Runge-Kutta methods considered below are assumed to be explicit. In order to proceed one step from y_n^i to y_{n+1}^i we have to compute each function f^i ($P+1$) times. Hence this is called the **$(P+1)$ -stage method**. If we denote by $z^i(t)$ the solutions

of $z^{i'}(t) = f^i(t, z^j(t))$ with the initial conditions $z^i(x) = y^i$ and put $h\Delta^i(x, y^j; h) = z^i(x+h) - z^i(x)$, then we have $\Phi^i(x, y^j; h) - \Delta^i(x, y^j; h) = h^p \varphi^i(x, y^j) + O(h^{p+1})$, where the $\varphi^i(x, y^j)$ are expressible in terms of the $f^i(x, y^j)$ and their (partial) derivatives. Various Runge-Kutta methods have been devised by searching for values of the α_r and β_{rs} that make p as large as possible for a given p (p is called the order of the method). When searching for these values of α_r and β_{rs} , we usually impose at least one of the following conditions: (1) α_r and β_{rs} are simple; (2) the truncation error is small; (3) the region of absolute stability (\rightarrow Section G) is large; (4) α_r and β_{rs} give smaller roundoff errors; (5) only a small computer memory is required. The ordered pairs (P, p) , where p is the highest order that can be attained by the $(P+1)$ -stage method, are $(P \leq 3, P+1)$, $(4, 4)$, $(5, 5)$, $(6, 6)$, $(7, 6)$, $(8, 7)$, $(9-10, 8)$, $(p+2 \leq (P+1) \leq (1/2)(p^2 - 2p + 4), p \geq 9)$. The following formulas are frequently used since they are accurate and have simple parameters: for $P = 1$ and $p = 2$, the formulas with $\alpha_0 = 0, \alpha_1 = 1, \beta_{10} = 1/2$ (modified Euler method), with $\alpha_0 = \alpha_1 = 1/2, \beta_{10} = 1$ (improved Euler method) and with $\alpha_0 = 1/4, \alpha_1 = 3/4, \beta_{10} = 2/3$ (Ralston's second-order method); for $P = 2$ and $p = 3$, the formulas with $\alpha_0 = 2/9, \alpha_1 = 1/3, \alpha_2 = 4/9, \beta_{10} = 1/2, \beta_{20} = 3/4, \beta_{21} = 3/4$ (Ralston's third-order method), and with $\alpha_0 = 1/4, \alpha_1 = 0, \alpha_2 = 3/4, \beta_{10} = 1/3, \beta_{20} = 2/3, \beta_{21} = 2/3$ (Heun's third-order method). For $P = 3, p = 4$, the formula with $\alpha_0 = \alpha_3 = 1/6, \alpha_1 = \alpha_2 = 1/3, \beta_{10} = \beta_{20} = \beta_{21} = 1/2, \beta_{30} = \beta_{32} = 1, \beta_{31} = 0$ is well known and is frequently referred to as "the fourth-order Runge-Kutta method" or "the Runge-Kutta method." It has various desirable features [8]. Gill's modification of the classical Runge-Kutta method (sometimes called the **Runge-Kutta-Gill method**) has some advantage in regard to roundoff errors and to the necessary computer memory size, while Ralston's second-, third-, and fourth-order methods have minimum error bounds in Lotkin's sense for the local truncation error [7]. There exist "substantially fifth-order" methods for $P = 4$ [9]. Today we frequently prefer to use higher-order methods, especially fifth-order methods, instead of lower-order methods, because the former require less computation time for solutions of given accuracy [10].

For the estimation of the local truncation error, the following two practical techniques are well known: (i) **one-step-two-half-steps error estimate**. If we let y_{n+1}^{12} and y_{n+1}^i denote the approximations that are computed with an m th-order method by taking two half-steps and one full step ($= h_n$), respectively, then an estimate of the local truncation error per half-step associated with y_{n+1}^{12} is given by the

formula

$$t_{n+1}^i \approx \gamma_m^i (h_n/2)^{m+1} \approx (y_{n+1}^{i2} - y_{n+1}^i)/2(1-2^m),$$

where we assume that γ_m^i does not vary much over the interval $[x_n, x_{n+1}]$. (ii) **The formula of embedding form.** The following formula of embedding form is more effective than the traditional method above. By use of the p th-order method $y_{n+1}^i = y_n^i + \sum_{r=0}^p \alpha_r k_r^i$ and the $(p+1)$ th-order method $y_{n+1}^{i*} = y_n^i + \sum_{r=0}^p \alpha_r^* k_r^i$, we obtain an estimate of the local truncation error in y_{n+1}^i as $t_{n+1}^i \approx y_{n+1}^i - y_{n+1}^{i*}$ [11–13]. At present, formulas of this type are known for $p = 2-8$, where the method for $p=5$ is said to be the most efficient. Recently, a similar method for the estimation of the global truncation error has been investigated [14]. In addition, multistep generalizations of explicit Runge-Kutta methods, which are known as **pseudo-Runge-Kutta methods**, have also been investigated [15].

E. Multistep Methods

A **linear multistep method** approximates given differential equations by difference equations $\rho(E)y_n^i = h\sigma(E)f_n^i$, where E is the operator of increasing n by 1, $\rho(\zeta) = \alpha_k \zeta^k + \alpha_{k-1} \zeta^{k-1} + \dots + \alpha_1 \zeta + \alpha_0$, $\sigma(\zeta) = \beta_k \zeta^k + \beta_{k-1} \zeta^{k-1} + \dots + \beta_1 \zeta + \beta_0$, $\alpha_k \neq 0$, and $|\alpha_0| + |\beta_0| \neq 0$. (If ρ and σ are of degree k in ζ , we speak of a **linear k -step method**.) By means of these difference equations we can determine y_{n+k}^i from $y_{n+k-1}^i, y_{n+k-2}^i, \dots, y_n^i$. Since the y_{n+k}^i are determined explicitly if $\beta_k = 0$ and implicitly if $\beta_k \neq 0$, the difference equations are called **explicit** and **implicit**, respectively. In the implicit case, if $|h| < |(\alpha_k/\beta_k)L|$, where L is a Lipschitz constant for $f^i(x, y^j)$, then the y_{n+k}^i can be calculated by successive substitutions. In order to obtain the y_n^i successively by means of a k -step method with $k \geq 0$, it is necessary, to begin with, to give the $k-1$ sets of m values y_1^i, \dots, y_{k-1}^i (called the **starting values**) in addition to the initial values $y_0^i = \eta^i$. To determine the starting values, Runge-Kutta methods, overall approximation formulas, etc., are ordinarily used. The number of times we have to compute the f^i to proceed one step from y_n^i to y_{n+1}^i is only 1 for an explicit case, while for an implicit case it is equal to the number of iterations required to secure the convergence of the successive substitutions (ordinarily, the step size h as well as the 0th approximation for y_{n+k}^i are chosen so that the convergence is attained after a few iterations). We have $\lim_{h \rightarrow 0, x_n = x} e_n^i = 0$ ($x \in [a, b]$) for any f^i and η^i and any starting values such that $\lim_{h \rightarrow 0} y_\mu^i = \eta^i$ ($\mu = 0, 1, \dots, k-1$), if and only if the polynomials ρ and σ satisfy the following two conditions: (i) **consistency**: $\rho(1) = 0$, $\rho'(1) = \sigma(1)$; (ii) **zero stability**: Every root

of $\rho(\zeta) = 0$ lies on or inside the unit circle, and every root lying on the unit circle is simple.

We call $t_n^i = (\rho(E)y^i(x_n) - h\sigma(E)y^{i*}(x_n))/\sigma(1)$ the **local truncation error**. For a consistent and stable method determined by (ρ, σ) there exist a real constant C_{p+1} ($\neq 0$) and an integer p (≥ 1) such that $t_n^i = h^{p+1} C_{p+1} y^{i(p+1)}(x_n)/\sigma(1) + O(h^{p+2})$; p is called the **order** of the method and $C \equiv C_{p+1}/\sigma(1)$ the **error constant**. For a given ρ satisfying (ii), σ is chosen to make the order as small as possible and then to make the error constant as small as possible. However, p cannot exceed $k+1$ if k is odd or $k+2$ if k is even; moreover, p can be equal to $k+2$ only if all the roots of $\rho(\zeta) = 0$ lie on the unit circle.

The following are examples of multistep methods.

(1) Explicit Methods.

(a) Adams-Bashforth methods.

$$k=1, \quad \rho(\zeta) = \zeta - 1, \quad \sigma(\zeta) = 1, \quad p=1,$$

$$C = 1/2 \quad (\text{Euler method});$$

$$k=2, \quad \rho(\zeta) = \zeta(\zeta - 1), \quad \sigma(\zeta) = (3\zeta - 1)/2,$$

$$p=2, \quad C = 5/12;$$

$$k=3, \quad \rho(\zeta) = \zeta^2(\zeta - 1),$$

$$\sigma(\zeta) = (23\zeta^2 - 16\zeta + 5)/12, \quad p=3,$$

$$C = 3/8;$$

etc.

(b) Midpoint rule.

$$k=2, \quad \rho(\zeta) = \zeta^2 - 1, \quad \sigma(\zeta) = 2\zeta,$$

$$p=2, \quad C = 1/6.$$

(c) Milne's predictor.

$$k=4, \quad \rho(\zeta) = \zeta^4 - 1,$$

$$\sigma(\zeta) = (8\zeta^3 - 4\zeta^2 + 8\zeta)/3,$$

$$p=4, \quad C = 7/90.$$

(2) Implicit Methods.

(a) Adams-Moulton methods.

$$k=1, \quad \rho(\zeta) = \zeta - 1, \quad \sigma(\zeta) = (\zeta + 1)/2,$$

$$p=2, \quad C = -1/12 \quad (\text{trapezoidal rule});$$

$$k=2, \quad \rho(\zeta) = \zeta(\zeta - 1),$$

$$\sigma(\zeta) = (5\zeta^2 + 8\zeta - 1)/12,$$

$$p=3, \quad C = -1/24;$$

etc.

(b) Milne's corrector (or the Milne-Simpson formula).

$$k=2, \quad \rho(\zeta) = \zeta^2 - 1, \quad \sigma(\zeta) = (\zeta^2 + 4\zeta + 1)/3,$$

$$p=4, \quad C = -1/90.$$

When an implicit formula (ρ, σ) is used to obtain y_{n+k}^i , the 0th approximation y_{n+k}^{i*} for y_{n+k}^i is usually determined by an explicit formula (ρ^*, σ^*) of the same order as (ρ, σ) (where (ρ^*, σ^*) itself may not necessarily be stable). This kind of combination of implicit and explicit methods is called a **predictor-corrector method** (or **PC method**), where the formula (ρ^*, σ^*) is called the **predictor** and (ρ, σ) the **corrector**. Typical combinations are the midpoint rule and the trapezoidal rule, Milne's predictor and Milne's corrector (this combination is called **Milne's method**), and an Adams-Bashforth method and an Adams-Moulton method of the same order. A predictor-corrector method has the advantage that the local truncation error (of the corrector) can be estimated in the course of calculation without extra computation. In fact, if the orders of the predictor (ρ^*, σ^*) and the corrector (ρ, σ) are equal to p and their error constants to C^* and C , respectively, then the local truncation error t_n^i can be estimated by $t_n^i = KD_n^i + O(h^{p+2})$ ($n = 0, 1, \dots$), where $D_n^i \equiv y_{n+k}^{i*} - y_{n+k}^i$ is the difference between the value y_{n+k}^{i*} at x_{n+k} obtained by the predictor and the y_{n+k}^i obtained by the corrector, and $K = \alpha_k^* C / [(C - C^*)\sigma^*(1)]$ [16].

The term **multistep methods** originates from the fact that these use the values of the dependent variables at more than two different mesh points in order to proceed one step. These are also called **multivalue methods** since they use more than one value of the dependent variable. The multivalue method is, however, a more general concept than the multistep method.

Linear multistep methods are not only examples of the PC method; they are also examples of the **variable-step variable-order algorithms** (VSVO algorithms), where the order of the formula as well as the step size are automatically chosen according to the behavior of the solution. In practical VSVO algorithms, the Adams-Bashforth-Moulton family of PC pairs of order 1 to 13 are usually used, and for solving stiff systems (\rightarrow Section G) those correctors with large regions of absolute stability are used. In these algorithms we use the multivalue method, which saves the information at different steps in a form convenient for the change of order and of step size. The multivalue method also facilitates error estimation and stability, and results in an efficient use of memory and reduction of the computational cost. For example, in Gear's algorithm the information required for computing y_{n+1} is saved in the following form: $\mathbf{y}_n = (y_n, hy_n', \dots, (h^k/k!)y_n^{(k)})$, where $y'(x)$ is the polynomial $P_{k,n}(x)$ interpolating $f_n, f_{n-1}, \dots, f_{n-k+1}$, where $y_n^{(i)} = d^{i-1}P_{k,n}(x)/dx^{i-1}|_{x=x_n}$ hold. All the local truncation error estimators are based essentially

on Milne's device. In the VSVO algorithms heuristics play an important role [2, 17, 18].

F. Extrapolation Methods

Let us assume that the numerical solution with the step size h at some fixed point x has the form

$$y(x, h) = y(x) + \sum_{i=1}^m \tau_i h^r + O(h^{r(m+1)}),$$

where r is a positive integer. Then we can approximate $y(x, h)$ by a function $R_m(x, h)$ with $(m+1)$ unknowns determined by the requirement that $R_m(x, h_j) = y(x, h_j)$, $j = 0, 1, 2, \dots, m$, $h_i > h_j$ ($i < j$) in order to approximate $y(x)$ by $R_m(x, 0)$. If $R_m(x, h)$ is a polynomial of degree mr in h , we call the foregoing method a **polynomial extrapolation method**, where $R_m(x, h) = y(x) + o(h^{r(m+1)})$ as h tends to 0. Defining $R_0^i = y(x, h_j)$ and $R_m(x, 0) = R_m^i$ for $j = i, i+1, \dots, i+m$, we can calculate the R_m^i by the recursion relation $R_m^i = R_{m-1}^{i+1} + (R_{m-1}^{i+1} - R_{m-1}^i) / ((h_i/h_{i+m})^r - 1)$, $m \geq 1$. It is well known that, for the following method (Gragg's method), there exists an asymptotic expansion with $r = 2$ [19]: $x_n = nh$, $\eta(0, h) = y(0)$, $\eta(x_1, h) = y_0 + hf(y_0, 0)$, $\eta(x_{n+1}, h) = \eta(x_n, h) + 2hf(\eta(x_n, h), x_n)$, $n = 1, 2, \dots, N-1$, where $x_N = x$, $y(x, h) = 1/2[\eta(x_{N-1}, h) + \eta(x_N, h) + hf(\eta(x_N, h), x_N)]$. If $R_m(x, h)$ is a rational function

$$R_m(x, h_j) = (p_0 + p_1 h + p_2 h^2 + \dots + p_n h^n) / (q_0 + q_1 h + q_2 h^2 + \dots + q_v h^v),$$

where $\mu = [m/2]$, $v = m - \mu = [(m+1)/2]$, $j = i, i+1, \dots, i+m$, we call this method a **rational extrapolation method**. For $r = 2$, the following formulas were derived by Bulirsch and Stoer [20]:

$$R_m^i = R_{m-1}^{i+1} + (R_{m-1}^{i+1} - R_{m-1}^i) / ((h_i/h_{i+m})^2 \times [1 - (R_{m-1}^{i+1} - R_{m-1}^i) / (R_{m-1}^{i+1} - R_{m-1}^2)] - 1),$$

$$m \geq 1, R_{-1}^i = 0, R_0^i = y(t, h_i).$$

G. Stability

Consider the application of the general k -step method at the n th point (which is consistent and 0-stable)

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \sum_{j=0}^k \beta_j f_{n+j}$$

to $y' = f(x, y)$, $y(x_0) = y_0$. Let \tilde{y}_n be the numerical solution at $x = x_n$. Let $\tilde{e}_n = y(x_n) - \tilde{y}_n$ be the global error, and let φ_n be the total error at the n th application. Then we find

$$\sum_{j=0}^k \alpha_j \tilde{e}_{n+j} = h \sum_{j=0}^k \frac{\partial f}{\partial y}(x_{n+j}, \xi_{n+j}) \beta_j \tilde{e}_{n+j} + \varphi_{n+k},$$

where ξ_{n+j} lies in the open interval whose endpoints are y_{n+j} and $y(x_{n+j})$. If we make two assumptions, $\partial f/\partial y = \lambda$ (const), $\varphi_n = \varphi$ (const), the above equation reduces to $\sum_{j=0}^k (\alpha_j - h\lambda\beta_j)\tilde{e}_{n+j} = \varphi$, whose general solution is given by

$$\tilde{e}_n = \sum_{s=0}^k d_s r_s^n - \varphi/h\lambda \sum_{j=0}^k \beta_j,$$

where the d_s are arbitrary constants and the r_s are the roots, assumed distinct, of the polynomial equation

$$\sum_{j=0}^k (\alpha_j - h\lambda\beta_j)r^j = 0.$$

We call the linear k -step method **absolutely stable** for a given $h\lambda$ if $|r_s| < 1$, $s = 1, 2, \dots, k$. On the other hand, we call the linear k -step method **relatively stable** for a given $h\lambda$ if $|r_s| < |r_1|$ (or $|r_s| < e^{\lambda h}$), $s = 2, 3, \dots, k$, where r_1 is the root corresponding to the theoretical solution. We call the region $S_a = \{h\lambda \mid |r_s| < 1, s = 1, 2, \dots, k\}$ (or $S_r = \{h\lambda \mid |r_s| < e^{\lambda h} \text{ (or } |r_1|), s = 2, 3, \dots, k\}$) in the complex plane the **region of absolute stability** (or the **region of relative stability**) of the linear k -step method. Also we call $S_a \cap R$ (or $S_r \cap R$) the **interval of absolute stability** (or the **interval of relative stability**) of the linear multistep method, where R is the real line. The explicit methods and the PC methods have a finite interval of absolute stability. The implicit methods usually have larger intervals of absolute stability than the corresponding explicit methods. The higher-order PC methods have smaller intervals, while Runge-Kutta methods do not. The PECE methods usually have larger intervals of stability than the corresponding PEC or P(EC)² methods, where P indicates an application of predictor, C an application of corrector, and E an evaluation of f [21, 22].

Let us consider the linear system $y' = Ay + \varphi(x)$, where A is an $m \times m$ constant matrix and $y(x)$, $y'(x)$, $\varphi(x) \in \mathbf{R}^m$. If A possesses m distinct eigenvalues $\lambda_t = \mu_t + i\nu_t$, $t = 1, 2, \dots, m$, the theoretical solution of this system is given by

$$y(x) = \sum_{t=1}^m K_t \exp((\mu_t + i\nu_t)x) C_t + \psi(x),$$

where K_t and C_t , $t = 1, 2, \dots, m$, are, respectively, arbitrary constants and the eigenvectors corresponding to λ_t and $\psi(x)$ is a particular solution. We call the linear system **stiff** if (i) $\mu_t < 0$, $t = 1, 2, \dots, m$, (ii) $s \gg 1$, where $s = \max_{1 \leq t \leq m} |\mu_t| / \min_{1 \leq t \leq m} |\mu_t|$. We call the non-linear system $y' = f(x, y)$, $y(x)$, $y''(x)$, $f(x, y) \in \mathbf{R}^m$ **stiff in an interval I of x** if, for every $x \in I$, the eigenvalues $\lambda_t(x)$ of the Jacobian matrix of f satisfy (i) and (ii). The ratio s is called the **stiffness ratio**. To solve stiff systems effectively a variety of methods with infinite stability

regions have been proposed. Some of them are:

- (1) **A-stability** (Dahlquist): $S_a \supseteq \{h\lambda \mid \operatorname{Re}(h\lambda) < 0\}$
- (2) **Stiff-stability** (Gear): $S_a \supseteq S_1 \cup S_2$, $S_1 = \{h\lambda \mid \operatorname{Re}(h\lambda) < -a < 0\}$, $S_2 = \{h\lambda \mid -a \leq \operatorname{Re}(h\lambda) \leq b, -c \leq \operatorname{Im}(h\lambda) \leq c, b \geq 0, c > 0\}$
- (3) **A(α)-stability** (Widlund): $S_a \supseteq \{h\lambda \mid -\alpha < \pi - \arg(h\lambda) < \alpha, \alpha \in (0, \pi/2)\}$
- (4) **A₀-stability** (Cryer): $S_a \supseteq \{h\lambda \mid \operatorname{Re}(h\lambda) < 0, \operatorname{Im}(h\lambda) = 0\}$.

The order p and the step number k of linear multistep methods are restricted by the following stability requirements:

- (i) **A-stability**: implicit, $p \leq 2$; trapezoidal rule is the most accurate method.
- (ii) **Stiff-stability**: implicit, $p \leq k$; backward differentiation formulas $\sum_{j=0}^k \alpha_j y_{n+j} = hf_{n+k}$ are stiffly stable for $p = k = 1, 2, \dots, 6$, 0-unstable for $k = 6$.
- (iii) **A(α)-stability**: implicit; there exist high-order A(0)-stable linear multistep methods. (A method is said to be **A(0)-stable** if it is A(α)-stable for some sufficiently small $\alpha \in (0, \pi/2)$.)

For the Runge-Kutta (P, p) methods, we can write

$$\tilde{e}_{n+1} = \left\{ 1 + h\lambda + (h\lambda)^2/2! + \dots + (h\lambda)^p/p! + \sum_{q=p+1}^{P+1} \gamma_q (h\lambda)^q \right\} \tilde{e}_n + \varphi_{n+1},$$

where $\partial f/\partial y = \lambda$ (const) and γ_q are functions of the coefficients of the method in use. We call a region $R = \{h\lambda \mid |1 + h\lambda + (h\lambda)^2/2! + \dots + (h\lambda)^p/p! + \sum_{q=p+1}^{P+1} \gamma_q (h\lambda)^q| < 1\}$ a **region of absolute stability of the Runge-Kutta (P, p) method**.

The implicit Runge-Kutta methods have a larger region of absolute stability than the corresponding explicit Runge-Kutta methods. Therefore the implicit Runge-Kutta methods are suitable for stiff equations, and the explicit Runge-Kutta methods are suitable for nonstiff or mildly stiff equations.

Recently, Yamaguti and others have pointed out that the instabilities occurring in the numerical solution of ordinary differential equations are closely connected to the phenomena of **chaos** studied by Li, Yorke, and others [23, 24].

H. Boundary Value Problems

A boundary value problem is generally formulated as the problem of obtaining functions $y^i(x)$ that satisfy the differential equations $y^{(i)}(x) = f^i(x, y^1(x), \dots, y^m(x))$ and boundary conditions $B_k(y^1(x_{n_1}), \dots, y^m(x_{n_1}); y^1(x_{n_2}), \dots, y^m(x_{n_2}); \dots; y^1(x_{n_s}), \dots, y^m(x_{n_s})) = 0$ ($i, k = 1, \dots, m$), where the f^i and B_k are given functions. If the f^i and B_k are linear in the y^i , we can

first calculate the solutions $y_0^i(x)$ of the differential equations under an appropriate initial condition, as well as a set of m independent solutions $y_l^i(x)$ ($l = 1, \dots, m$) of the homogeneous differential equations (say, under the initial conditions $y_l^i(a) = \delta_l^i$ at some point $x = a$), and then substitute the expression for the desired solution $y^i(x) = y_0^i(x) + \sum_{l=1}^m \alpha_l y_l^i(x)$ in the boundary conditions to obtain simultaneous linear equations for the unknowns α_l (\rightarrow 302 Numerical Solution of Linear Equations). No universally powerful method is known for the case where the f^i or the B_k or both are nonlinear. Ordinarily, we resort to the trial-and-error method of solving the differential equations iteratively under different initial conditions until the solution fully satisfies the boundary conditions, or to approximating the differential operators by suitable difference operators to obtain a set of (generally nonlinear) simultaneous equations approximating at the same time the differential equations and the boundary conditions. For related topics \rightarrow 298 Numerical Computation of Eigenvalues; 315 Ordinary Differential Equations (Boundary Value Problems); [25–27].

I. Methods Other than Difference Methods

Besides difference methods there are frequently used methods for finding in a given finite-dimensional function space a function that best satisfies the differential equations as well as the initial or boundary conditions. Denote the equations by $L[y(x)] = 0$ and assume the conditions to be linear. We choose a function $y_0(x)$ that satisfies the conditions and that is considered to approximate the exact solution, and also functions $y_l(x)$ ($l = 1, \dots, q$) that are considered to represent the typical deviations of $y_0(x)$ from the exact solution and each of which satisfies the homogeneous conditions. We then determine the α_l in such a way that $y(x) = y_0(x) + \sum_{l=1}^q \alpha_l y_l(x)$ best satisfies the differential equations. Corresponding to different interpretations of the words “best satisfy” there are different methods. The **collocation method** determines the α_l so as to nullify the values of $L[y(x)]$ at some prescribed points x_i ; the **method of least squares** minimizes the integral of $|L[y(x)]|^2$ over the considered region; the **Galerkin method** makes $L[y(x)]$ orthogonal to every $y_l(x)$ ($l = 1, \dots, q$); and the **Ritz method** considers the variational problem $\delta J[y(x)] = 0$ whose Euler equation is $L[y(x)] = 0$ (\rightarrow 46 Calculus of Variations F), if such a problem exists, and determines the α_l so as to have $J[y(x)]$ take an extremum value with $y(x) = y_0(x) + \sum_{l=1}^q \alpha_l y_l(x)$.

304 (XV.9) Numerical Solution of Partial Differential Equations

A. General Remarks

The numerical solution of partial differential equations became practical in the 1950s with the advent of automatic digital computers. Nowadays, by means of modern high-performance computers, the numerical solution of partial differential equations is carried out extensively and often on a very large scale for problems in physics, engineering, and other fields of applied analysis, in order to obtain approximate solutions of rigorous equations or to simulate real phenomena by means of numerical experiments. Various numerical-solution schemes have been proposed, applied, and studied, and programming techniques required to implement numerical solutions are being invented regularly; some are of a general nature, and others are devised for particular problems. The variational method, which includes the Ritz-Galerkin method and the finite element method, and

the difference method deserve special mention here because of their generality and scope of application.

B. The Ritz-Galerkin Method

Having been applied mainly to boundary value problems for elliptic partial differential equations, the **Ritz method** is a classical method, which has been used since the old era of mechanical calculators, and is mathematically nothing other than the †direct method in the calculus of variations (→ 46 Calculus of Variations F) applied to †variational problems that are equivalent to the original boundary value problems. In order to exemplify the method, let Ω be a bounded domain in \mathbb{R}^N with piecewise smooth boundary S , and consider the Dirichlet boundary value problem comprised of the Poisson equation

$$\Delta u = -f \quad (1)$$

and the boundary condition

$$u|_S = \beta. \quad (2)$$

Here f and β are given functions on Ω and S , respectively. (In the following, given functions are assumed to be sufficiently smooth.) The boundary value problem (1), (2) is equivalent to the variational problem of minimizing the †functional

$$J[u] = \frac{1}{2}a(u, u) - (u, f) \quad (3)$$

within the set $D(J)$ of **admissible functions** u subject to (2). In (3) the following notation is used:

$$a(u, v) = (\nabla u, \nabla v)_{L_2(\Omega)} = \int_{\Omega} \nabla u \cdot \nabla v \, dx$$

and

$$(u, v) = (u, v)_{L_2(\Omega)} = \int_{\Omega} uv \, dx,$$

while

$$D(J) = \{u \in L_2(\Omega) \mid \nabla u \in L_2(\Omega), \quad u|_S = \beta\}.$$

This variational problem is further reduced to the condition:

$$u \in D(J), \quad a(u, \varphi) = (f, \varphi) \quad (\forall \varphi \in V), \quad (4)$$

where V stands for the †Sobolev space $H_0^1(\Omega)$ (→ 168 Function Spaces B), that is,

$$V = H_0^1(\Omega) = \{u \in L_2(\Omega) \mid \nabla u \in L_2(\Omega), \quad u|_S = 0\}.$$

Note that V is equal to $D(J)$ with $\beta \equiv 0$. The condition (4) is often called a **weak form of the boundary value problem**. In applying the Ritz

method to this problem, we introduce unknown parameters $\alpha_1, \alpha_2, \dots, \alpha_n$ and set the approximate solution u_n in the form

$$u_n = F(x; \alpha_1, \alpha_2, \dots, \alpha_n) \in D(J)$$

and minimize $J[u_n]$ as a function of the n variables $\alpha_1, \alpha_2, \dots, \alpha_n$. A standard way to form u_n is to choose first a $b \in D(J)$ subject to the inhomogeneous boundary condition and $\varphi_1, \varphi_2, \dots, \varphi_n \in V$ subject to homogeneous boundary condition, and then to set

$$u_n = b + \alpha_1 \varphi_1 + \alpha_2 \varphi_2 + \dots + \alpha_n \varphi_n. \quad (5)$$

The functions φ_j ($j = 1, 2, \dots, n$) are called **basis functions** or **coordinate functions** in the Ritz method. Denoting by D_n the set of all possible functions appearing on the right-hand side of (5) and by V_n the linear space generated by $\varphi_1, \varphi_2, \dots, \varphi_n$, we can state the condition to determine the approximate solution u_n as:

$$u_n \in D_n$$

$$a(u_n, \varphi) = (f, \varphi) \quad (\forall \varphi \in V_n). \quad (6)$$

Thus the Ritz method is a kind of **projective approximation method** which approximates the weak equation (4) by its projection on a finite-dimensional space V_n . The condition (6) is equivalent to the equations

$$a(u_n, \varphi_j) = (f, \varphi_j) \quad (j = 1, 2, \dots, n). \quad (7)$$

Particularly when $\beta \equiv 0$ in (2), D_n coincides with V_n , and the equations (7) that determine the coefficients α_j are reduced to a linear equation

$$K\alpha = \gamma \quad (8)$$

for $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)$, where the matrix $K = (K_{ij})$ and the vector $\gamma = (\gamma_1, \gamma_2, \dots, \gamma_n)$ are given respectively by $K_{ij} = a(\varphi_i, \varphi_j)$ and $\gamma_j = (f, \varphi_j)$. Solving (8) numerically by the †Gauss elimination method or by †iteration, one eventually obtains the approximate solution u_n by the Ritz method. The Ritz method is also applicable, for instance, to the eigenvalue problem $\Delta u = \lambda u, u|_s = 0$, since this eigenvalue problem is equivalent to the variational problem of finding a stationary **Rayleigh's quotient** $R[u] = a(u, u)/(u, u)$ with V as the set of admissible functions. In the approximation to restrict the admissible functions to V_n , the approximate eigenvalue $\lambda^{(n)}$ is determined through the matrix eigenvalue problem

$$K\alpha = \lambda^{(n)} M\alpha, \quad (9)$$

where the matrix K is as above and the matrix $M = (M_{ij})$ is given by $M_{ij} = (\varphi_i, \varphi_j)$. Sometimes, optimization of $J[u_n]$ or $R[u_n]$ is carried out more directly, e.g., by the †gradient method, particularly when u_n contains free parameters α_j in some nonlinear way.

Many studies have been made of convergence and error estimation for the Ritz method in general (\rightarrow e.g., [1–4]). For instance, it is known that, if $\beta = 0$, $f \in L^2(\Omega)$, and $\{\varphi_1, \varphi_2, \dots, \varphi_n, \dots\}$ spans a linear subspace dense in $V = H_0^1(\Omega)$, then the approximate solution u_n obtained through (6) (or through (12) below) converges to the rigorous solution in the H^1 -topology (and hence in the L^2 -topology). Nevertheless, success in using the method in practical applications can be gained only by a clever choice of trial functions. A typical but systematic example of such a choice is made by the finite element method (\rightarrow Section C).

We proceed to the **Galerkin method** [1]. Suppose that we are to solve the equation

$$L[u] = \Delta u + (b \cdot \nabla)u = -f, \quad (10)$$

which is the equation in (1) perturbed by a lower-order term (the convection term). Here $b = (b_1(x), \dots, b_n(x))$ and $(b \cdot \nabla)u = \sum_j b_j(x)(\partial u / \partial x_j)$. For simplicity, the boundary condition (2) is assumed to be homogeneous (i.e., $\beta \equiv 0$). Although the boundary value problem (10), (2) cannot be reduced to a variational problem since (10) is not symmetric, it is equivalent to its weaker form

$$a(u, \varphi) - ((b \cdot \nabla)u, \varphi) = (f, \varphi) \quad (\forall \varphi \in V), \quad (11)$$

provided that $u \in V$. Note that (11) is obtained from $(L[u] + f, \varphi)_{L_2} = 0$ by transforming $(L[u], \varphi)$ through integration by parts. Actually, this boundary value problem has a unique solution u for any $f \in L_2(\Omega)$ if $|\operatorname{div} b|$ is sufficiently small. According to the Galerkin method as applied to the present problem, one replaces V by V_n in (11) and determines the approximate solution $u_n = \alpha_1 \varphi_1 + \dots + \alpha_n \varphi_n \in V_n$ by the condition

$$a(u_n, \varphi) - ((b \cdot \nabla)u_n, \varphi) = (f, \varphi) \quad (\forall \varphi \in V_n), \quad (12)$$

which is equivalent to the equations

$$a(u_n, \varphi_j) - ((b \cdot \nabla)u_n, \varphi_j) = (f, \varphi_j) \quad (j = 1, 2, \dots, n). \quad (13)$$

Sometimes it is convenient to project $(L[u] + f, \varphi) = 0$ onto the finite-dimensional space and to deal directly with $(L[u_n] + f, \varphi_j) = 0$ ($j = 1, 2, \dots, n$). When the coefficients of the equation and the given function f are periodic in space variables and when sine or cosine functions are chosen as basis functions, the Galerkin method turns out to be the same as the so-called Fourier approximation method and can be efficiently implemented with the aid of a †fast Fourier transform (FFT) to yield the required Fourier coefficients numerically [5].

The Galerkin method can be applied to the numerical solution of evolution equations, namely, in order to approximate time-

dependent solutions. This is exemplified through the following initial-boundary value problem for the diffusion equation (heat equation):

$$\frac{\partial u}{\partial t} = \Delta u \quad (t \geq 0, x \in \Omega) \quad (14)$$

with the homogeneous boundary condition

$$u|_s = 0 \quad (15)$$

and the initial condition

$$u|_{t=0} = a(x) \quad (x \in \Omega). \quad (16)$$

We first set the required approximate solution $u_n = u_n(t, x)$ in terms of the basis functions $\varphi_1, \varphi_2, \dots, \varphi_n$ of V_n as

$$u_n = \alpha_1(t)\varphi_1 + \alpha_2(t)\varphi_2 + \dots + \alpha_n(t)\varphi_n, \quad (17)$$

and then determine the coefficients $\alpha_1(t), \alpha_2(t), \dots, \alpha_n(t)$ from the conditions

$$\frac{d}{dt}(u_n, \varphi) = -a(u_n, \varphi) \quad (t \geq 0, \forall \varphi \in V_n) \quad (18)$$

and

$$(u_n(0), \varphi) = (a, \varphi) \quad (\forall \varphi \in V_n). \quad (19)$$

Since (18) is equivalent to the equations

$$\frac{d}{dt}(u_n, \varphi_j) = -a(u_n, \varphi_j) \quad (j = 1, 2, \dots, n),$$

the vector function $\alpha(t) = (\alpha_1(t), \alpha_2(t), \dots, \alpha_n(t))$ is obtained by solving the ordinary differential equation

$$M \frac{d}{dt} \alpha = -K \alpha, \quad (20)$$

where the matrices M and K are those in (8) and (9). The initial value $\alpha(0)$ of α should be given in accordance with (19). Sometimes the procedure above is called a **semidiscrete approximation** based on the Galerkin method. Obviously, this method can be applied to more general evolution equations, for instance, to the **diffusion-convection equation**

$$\frac{\partial u}{\partial t} = L[u] = \Delta u + (b \cdot \nabla)u, \quad (21)$$

which governs time-dependent states corresponding to stationary states subject to (10). As a concrete example, we can refer to the finite element approximation for evolution equations described in Section D. If the geometry of Ω is simple enough, e.g., for 1-dimensional Ω , one can adopt eigenfunctions of $L[\]$ as the basis functions; the resulting version of the semidiscrete Galerkin method is called a **spectral method**.

In order to obtain $u_n(t)$ one has to carry out numerical integration for (20), discretizing the time variable. The Galerkin approxima-

tion with discretization of the space and time variables is called a **full discrete approximation**. Finally, an advantage of the Ritz-Galerkin method is that if the boundary condition imposed on rigorous solutions is a natural boundary condition, then the admissible functions and particularly the basis functions need not satisfy it [4].

C. Finite Element Methods for Boundary Value Problems

In recent years the method of numerical solution of partial differential equations most extensively employed in structural mechanics and many other fields of engineering has been the **finite element method**. In its standard form, the finite element method can be regarded, at least mathematically, as a type of Ritz-Galerkin method that adopts as its basis functions piecewise polynomials of low degree and with narrow supports. Although the idea leading to the finite element method can be traced back to a paper by R. Courant in 1943 (*Bull. Amer. Math. Soc.*), the method acquired its popularity in the late 1950s when it was rediscovered by engineers on the basis of mechanical considerations [6]. Here we apply the method to the boundary value problem (1), (2), assuming that $\beta = 0$ and Ω a polygonal domain in \mathbf{R}^2 [7–9]. First, $\Omega = \Omega \cup S$ is divided into small triangles of which the length of any side does not exceed $h > 0$. Each triangle T appearing in this decomposition of $\bar{\Omega}$ is called a **triangular element**, or simply an **element** (following the terminology in structural mechanics), and we denote the set of all triangular elements by \mathcal{T}_h , h being equal to $\max_{T \in \mathcal{T}_h} \{ \text{the longest side of } T \}$. The set of all **nodal points**, i.e., the vertices of the triangular elements, is denoted by N , and we put

$$N_i = \{ P \in N \mid P \in \Omega \} = \{ P_1, P_2, \dots, P_n \}. \quad (22)$$

Then a standard choice of admissible functions is to adopt as V_n in (6) the following $V_h \subset V = H_0^1(\Omega)$:

$$V_h = \{ v_h \in C(\bar{\Omega}) \mid v_h \text{ is linear on each element} \\ \text{and } v_h|_s = 0 \}, \quad (23)$$

namely, V_h is the set of all elementwise linear continuous functions satisfying the boundary condition. Now the approximate solution $u_h \in V_h$ is determined by the condition

$$a(u_h, \varphi_h) = (f, \varphi_h) \quad (\forall \varphi_h \in V_h). \quad (24)$$

A basis of V_h is formed by pyramidal functions φ_j ($j = 1, 2, \dots, n$) $\in V_h$ such that

$$\varphi_j(P_j) = 1 \quad \text{and} \quad \varphi_j(Q) = 0 \quad (Q \in N \setminus \{P_j\}). \quad (25)$$

In order to obtain u_h , one has to solve (8) numerically for α . Since the support of φ_j is confined to elements adjacent to P_j , the matrix K turns out to be a sparse matrix of **multi-diagonal type**, and hence particular elimination procedures can be applied with high efficiency. In the finite element method, the matrix K is often called the **stiffness matrix**. The convergence of u_h to u as $h \rightarrow 0$ is guaranteed if \mathcal{T}_h ($0 < h \leq h_0$) satisfies a certain regularity condition. For instance, if any angle of a triangle T is not smaller than $\theta_0 > 0$, then u_h converges in the $H^1(\Omega)$ -topology. Moreover, when Ω is convex, it holds that

$$\begin{aligned} \|u - u_h\|_{H^1} &\leq Ch \|f\|_{L_2}, \\ \|u - u_h\|_{L_2} &\leq Ch^2 \|f\|_{L_2} \end{aligned} \quad (26)$$

[7, 9]. Uniform convergence of u_h to u and L_∞ -estimation of the error have also been established (e.g., [7, chap. 3]). u_h is subject to the maximum principle, provided that the triangulation \mathcal{T}_h is of acute type. Here, \mathcal{T}_h is said to be of **acute type** (or of **strongly acute type**) if any angle θ of $T \in \mathcal{T}_h$ is in $0 < \theta \leq (\pi/2)$ ($0 < \theta \leq \theta_1 < (\pi/2)$). To acquire higher accuracy, more sophisticated admissible functions that are piecewise polynomials of higher degree are used. To take account of curved boundaries, several devices, including the **isoparametric method**, have been proposed.

In dealing with biharmonic equations or other equations of higher order, one can conveniently apply a modified version of the finite element method of **mixed type** or of **nonconforming type**; in the latter the approximate solution is sought within a class of functions which are of less regularity at the interface of elements and hence do not belong to the domain of the original variational problem. i.e., which are not admissible in the classical sense [10, 11].

D. Finite Element Methods for Initial Value Problems

The most basic type of finite element method applicable to evolution problems is described here, and concerns the initial boundary value problem (14)–(16), assuming that Ω is the same as in Section B [8, 9]. In the semidiscrete finite element approximation one uses the functions φ_j of the preceding section as the basis for the approximate solution, now denoted by u_h , and then determines u_h through (17)–(19) with V_n replaced by V_h . Then u_h converges to u as $h \rightarrow 0$, provided that the triangulation \mathcal{T}_h is regular. Furthermore, under the same condition that makes (26) hold, the error is given by the fol-

lowing estimate [12]:

$$\|u - u_h\|_{L_2} \leq Ch^2 \|a\|_{L_2/t} \quad (t > 0), \quad (27)$$

which reflects the smoothing property of the diffusion equation. In the terminology of the finite element method, the matrix M in (20) is called the **mass matrix**. In order to gain a fully discrete finite element approximation $u_{\tau,h}$ for u , one discretizes the time variable with the \dagger mesh length τ and solves the difference analog of (20), i.e., either

$$M(\alpha(t + \tau) - \alpha(t))/\tau = -K\alpha(t) \quad (28)$$

or

$$M(\alpha(t + \tau) - \alpha(t))/\tau = -K\alpha(t + \tau), \quad (29)$$

where t is restricted to $t = k\tau$ ($k = 0, 1, 2, \dots$).

The difference schemes (28) and (29) are of **forward type** and of **backward type**, respectively. From (29) follows $\|\alpha(k\tau)\| \leq \|\alpha(0)\|$, and consequently $\|u_{\tau,h}(t)\|_{L_2} \leq C\|a\|_{L_2}$. In the generally accepted terminology, the approximation is **stable** if for each $T > 0$ there exists a positive constant C_T depending on T such that

$$\|u_{\tau,h}(t)\| \leq C_T \|a\| \quad (0 \leq t = k\tau \leq T). \quad (30)$$

Thus the approximation through (29) is unconditionally stable, while the one through (28) is stable only under certain conditions on the triangulation \mathcal{T}_h and on the time mesh τ . For instance, the forward scheme (28) is stable if \mathcal{T}_h is regular and satisfies the **inverse assumption**

$$\sup_{0 < h \leq h_0} \max_{T \in \mathcal{T}_h} \frac{h}{(\text{longest side of } T)} < +\infty,$$

and if the ratio τ/h^2 is sufficiently small [13, 14].

Sometimes, the mass matrix M in (28) and (29) is modified by the following procedure, called **mass lumping**: For each P_j , one joins alternately the center of gravity of the elements with P_j as one of their vertices and the middle point of the sides with P_j as one of their endpoints, thus forming a closed broken line Γ_j surrounding P_j . We denote by $\bar{\varphi}_j$ the characteristic function of the polygonal domain B_j bounded by Γ_j . When mass lumping is applied, the matrix M is replaced by the matrix $\bar{M} = ((\bar{\varphi}_i, \bar{\varphi}_j))$. Generally, mass lumping relaxes the conditions for the stability and the maximum principle to hold, although it may lower the accuracy to some extent (H. Fujii, *Proc. US-Japan Seminar*, Univ. Tokyo Press, 1973). Usually, schemes without mass lumping are called **consistent mass schemes**.

In principle, there is no difficulty in applying the finite element method to the diffusion-convection equation (21). However, when $\|b\|$ is large, the stability condition becomes strin-

gent. To meet these difficulties, M. Tabata, T. Ikeda [15], and others have devised some schemes that enjoy better stability, the maximum principle, and even the law of conservation of mass by improving mass lumping and introducing the idea of an upstream approximation or an artificial viscosity for discretizing the convection term. Moreover, finite element methods are currently being applied to wave equations, the Navier-Stokes equations, and various other evolution equations.

E. Difference Methods for Boundary Value Problems

In difference methods for solving partial differential equations we reduce the original equation to its **difference analog**, replacing differential quotients of the unknown function by the corresponding difference quotients. The difference analog, usually a system of algebraic equations, is then solved numerically, yielding the desired approximate solution. Since the last part of the method, i.e., the numerical solution of the difference analog, requires a large amount of computation, difference methods were not feasible until the development of automatic computers.

In terms of the variable x , difference approximations for the derivative df/dx are the **forward difference**

$$(D_x^h f)(x) = (f(x+h) - f(x))/h,$$

the **backward difference**

$$(D_x^h f)(x) = (f(x) - f(x-h))/h,$$

and the **central difference (symmetric difference)**

$$(\delta_x^h f)(x) = (f(x+h) - f(x-h))/2h.$$

In order to exemplify the difference method applied to boundary value problems, we return to equations (1) and (2), supposing that Ω is a 2-dimensional square $Q = \{(x, y) | 0 < x < 1, 0 < y < 1\}$ [1, 16–18]. Then we cover $Q \cup S$ by a **square net** (lattice, grid) with mesh length $h = 1/N$, for N a large integer. The set of net points $P_{m,n} = (mh, nh)$ lying in Q is denoted by Ω_h , and S_h is the set of net points on S . We want to have a net function u_h on $R_h = \Omega_h \cup S_h$ that approximates the solution u of (1) and (2), where u_h is determined by the difference equation

$$\Delta_h u_h(x, y) = -f(x, y) \quad ((x, y) \in \Omega_h), \quad (31)$$

and the boundary condition

$$u_h(x, y) = \beta(x, y) \quad ((x, y) \in S_h). \quad (32)$$

Here Δ_h is a difference operator, the 5-point

difference analog of Δ , which is defined by

$$\begin{aligned} \Delta_h \varphi &= D_x^h D_x^h \varphi + D_y^h D_y^h \varphi \\ &= (\varphi(x+h, y) + \varphi(x-h, y) + \varphi(x, y+h) \\ &\quad + \varphi(x, y-h) - 4\varphi(x, y))/h^2. \end{aligned}$$

In view of the maximum principle for net functions on R_h , it is seen that (31) and (32) admit only $u_h = 0$ as a solution if $f = \beta = 0$, which implies that the solution u_h of (31) and (32) exists uniquely for all f and β . When we are concerned with the convergence of u_h to u as $h \rightarrow 0$, we have to consider (31) and (32) for all small $h > 0$. Such a family of difference equations is called a **difference scheme**. Actually, u_h obtained through (31) and (32) converges to u as $h \rightarrow 0$, and we can say that the difference scheme (31) and (32) is convergent. In general, the order of the error $u - u_h$ depends on the smoothness of u . For instance, if $u \in C^4(\bar{\Omega})$, then $|u - u_h| \leq Ch^2$ holds uniformly on R_h . When the asymptotic behavior of the error is known to satisfy $u - u_h = wh^2 + o(h^2)$ for some $w = w(x, y)$, it is possible to attain a higher accuracy by eliminating the h^2 -order term if we compute u_h for two different values of h and form an appropriate linear combination of the u_h thus obtained (Richardson's extrapolation; \rightarrow e.g., [17]). The convergence of difference schemes applied to boundary value problems is not affected if rectangular nets are used instead of square nets. Many techniques have been devised to treat curved boundaries. There have been attempts recently to map Ω into a domain Q of simpler geometry, say, a rectangular one, and then discretize the arising partial differential equations with variable coefficients in Q (e.g., J. F. Thompson et al., *J. Comput. Phys.*, 1982.) Moreover, when information regarding the location and nature of singularities of solutions is available, one can refine the net near these points.

The difference analog of elliptic equations described above is a system of linear equations with the values of the u_h as its unknowns. Since the coefficient matrix of this system is of multidagonal type, direct elimination methods can be efficiently applied to solve it. Particularly, some elimination algorithms employing vector computations have been invented [19]. Iteration methods of the Gauss-Seidel type can also be applied, where acceleration of convergence by SOR is effective (\rightarrow 302 Numerical Solution of Linear Equations C).

F. Difference Methods for Initial Value Problems

To demonstrate characteristics of the difference method applied to evolution equa-

tions [17, 20, 21], we first consider the initial boundary value problem (14)–(16) for the diffusion equation supposing that $\Omega = (0, 1)$, a 1-dimensional interval. Then we cover $Q = [0, \infty) \times \bar{\Omega}$ by a rectangular net $t = n\tau$ ($n = 0, 1, 2, \dots$) and $x = jh$ ($j = 0, 1, \dots$) with mesh lengths $\Delta t = \tau$ and $\Delta x = h$. The value of the approximate function $u_{\tau,h}$ at the net point $(n\tau, jh)$ is denoted by U_j^n . Then the simplest **difference scheme of forward type** for (14) is written as

$$\frac{U_j^{n+1} - U_j^n}{\tau} = \frac{U_{j+1}^n + U_{j-1}^n - 2U_j^n}{h^2}. \quad (33)$$

Namely, we adopt the difference operator $L_{\tau,h}[\] = D_t - D_x^h D_x^h$ as the difference analog of $(\partial/\partial t) - (\partial^2/\partial x^2)$. Equation (33) is **consistent** in the sense that $L_{\tau,h}[u] = \text{"the residual of } u\text{"} \rightarrow 0$ ($\tau, h \rightarrow 0$) for any smooth solution u of (14). This is the case also with the **difference scheme of backward type**

$$\frac{U_j^{n+1} - U_j^n}{\tau} = \frac{U_{j+1}^{n+1} + U_{j-1}^{n+1} - 2U_j^{n+1}}{h^2}. \quad (34)$$

To compute the approximate solution $U^n = \{U_j^n | 0 \leq j \leq N\}$, (33) or (34) must be combined with the approximate initial condition corresponding to (16), say $U_j^0 = a(jh)$, and with the boundary condition $U_0^n = U_N^n = 0$. Then one can proceed from U^0 to U^1 , from U^1 to U^2 , and so on. Actually, (33) is rewritten in the form

$$U_j^{n+1} = \lambda U_{j+1}^n + \lambda U_{j-1}^n + (1 - 2\lambda)U_j^n, \quad (35)$$

with $\lambda = \tau/h^2$, which gives U^{n+1} explicitly in terms of U^n . Hence (33) is an **explicit scheme**. On the other hand, in order to acquire U^{n+1} from U^n according to (34), it is necessary to solve a system of linear equation with U^{n+1} as its unknown. Hence (34) is an **implicit scheme**. Since the coefficient matrix of the system of linear equations to determine U^{n+1} according to (34) is tridiagonal, one can employ a particularly efficient elimination algorithm.

We introduce the maximum norm $\|\varphi_h\|_h = \max_{R_h} |\varphi(jh)|$ for net functions φ_h on $R_h = \Omega_h \cup S_h = \{x = jh | 0 \leq j \leq N\}$. Then, as is obvious from (35), the approximate solution $U^n = u_{\tau,h}(n\tau)$ obtained through (33) satisfies $\|U^n\|_h \leq \|U^0\|_h$ ($n = 0, 1, \dots$), provided that

$$0 < \lambda = \frac{\tau}{h^2} \leq \frac{1}{2}. \quad (36)$$

Generally, a difference scheme approximating an initial value problem is said to be **stable** if the approximate solution $u_{\tau,h}$ for the initial value $a_h = u_{\tau,h}(0)$ satisfies, for small τ and h ,

$$\|u_{\tau,h}(t)\|_h \leq M_T \|a_h\|_h \quad (0 \leq t = n\tau \leq T) \quad (37)$$

for any $T > 0$, M_T being a constant depending

on T . **Lax's equivalence theorem** asserts that if the original initial value problem is well-posed and if the approximating difference scheme is consistent, then the stability of the difference scheme is necessary and sufficient for the convergence of the approximate solution $u_{\tau,h}$ to the rigorous solution u as $\tau, h \rightarrow 0$. For instance the explicit difference scheme (33) for the 1-dimensional diffusion equation is convergent under the mesh condition (36). On the other hand, the implicit scheme (34) is unconditionally stable and hence is convergent. Many difference schemes more sophisticated than (33) and (34), of higher accuracy or with other favorable properties, have been proposed and studied. All these difference schemes can be generalized to the case of many-dimensional Ω . For instance, if $\Omega \subset \mathbf{R}^2$, then by means of the difference operator Δ_h in (31), the forward scheme and the backward scheme are given by $D_t U^n = \Delta_h U^n$ and $D_t U^n = \Delta_h U^{n+1}$, respectively. The former is stable if $0 < \lambda = \tau/h^2 \leq 1/4$, while the latter is unconditionally stable. Moreover, in a method called the **ADI method** (alternating direction implicit method) one introduces $U^{n+1/2}$ on **fractional steps** $t = n\tau + \tau/2$ and discretizes (14) as

$$\begin{aligned} \frac{U^{n+1/2} - U^n}{\tau/2} &= D_x^h D_x^h U^n + D_y^h D_y^h U^{n+1/2}, \\ \frac{U^{n+1} - U^{n+1/2}}{\tau/2} &= D_x^h D_x^h U^{n+1/2} + D_y^h D_y^h U^{n+1/2}. \end{aligned} \quad (38)$$

Then, starting from U^0 , the computation goes as $U^0 \rightarrow U^{1/2} \rightarrow U^1 \rightarrow \dots \rightarrow U^n \rightarrow U^{n+1/2} \dots$ by solving at each step alternatively a difference equation implicit with respect to x and y , for which a particular elimination method can be used with good efficiency. Furthermore, the ADI method is unconditionally stable. Various types of fractional-step method that generalize the ADI method have been proposed [12, 17].

We now proceed to hyperbolic equations. First consider the Cauchy problem where the spatial domain is the whole \mathbf{R}^1 . Noting that the wave equation $v_{tt} = v_{xx}$, for instance, can be rewritten as

$$\frac{\partial u}{\partial t} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \frac{\partial u}{\partial x}$$

by putting $u = {}^t(v_t, v_x)$, we here deal with a hyperbolic system of the form

$$\frac{\partial u}{\partial t} = A \frac{\partial u}{\partial x}, \quad (39)$$

where the unknown u is an m -vector $u = {}^t(u_1, u_2, \dots, u_m)$, and A is a constant $m \times m$ matrix that is supposed to be real and symmetric. For hyperbolic equations, explicit schemes are generally preferred, and as a typ-

ical one we mention the **Friedrichs scheme**. In the Friedrichs scheme applied to (39), the approximate solution $U = {}^t(U_1, U_2, \dots, U_m)$ is determined by

$$\frac{U(t + \tau, x) - \frac{1}{2}(U(t, x + h) + U(t, x - h))}{\tau} = A \delta_x^h U(t, x). \quad (40)$$

Here t is restricted to $t = n\tau$ ($n = 0, 1, \dots$), while x is regarded as a variable ranging over \mathbf{R}^1 . Introducing translation operators T_h and T_{-h} by

$$T_h: \varphi(x) \rightarrow \varphi(x + h) \quad \text{and} \quad T_{-h}: \varphi(x) \rightarrow \varphi(x - h),$$

we obtain from (40)

$$U(t + \tau, \cdot) = S_h U(t, \cdot), \quad (41)$$

where, with the mesh ratio $\lambda = \tau/h$, S_h is given by

$$S_h = \left(\frac{1}{2} + \frac{\lambda}{2} A \right) T_h + \left(\frac{1}{2} - \frac{\lambda}{2} A \right) T_{-h}. \quad (42)$$

Generally, if a difference scheme is reduced to the form of (41), then the operator S_h , which yields evolution of the solution of the difference equation for one time step, is called the **amplification operator** of the scheme. The stability of the difference scheme is implied by the uniform boundedness of the operator norm $\|S_h^n\|$ of S^n acting in the Hilbert space $(L_2(\mathbf{R}^1))^m$ for $0 \leq n \leq T/\tau$. Consequently, the scheme is stable if $\|S_h\| \leq 1 + C\tau$, C being a constant. The symbol $\tilde{S}_h(\xi)$ of S_h with respect to the Fourier transform is called the **amplification matrix** of the scheme. The L_2 -stability of the scheme mentioned above is equivalent to the uniform boundedness of the matrix norm $\|\tilde{S}_h^n(\xi)\|$ for $0 \leq n\tau \leq T$ and $\xi \in \mathbf{R}^1$. Therefore, denoting by $r_h(\xi)$ the spectral radius of $\tilde{S}_h(\xi)$, one can give a necessary condition for the stability by $|r_h(\xi)| \leq 1 + C\tau$, which is called the **von Neumann condition**. Concerning general criteria for the uniform boundedness of powers of $\tilde{S}_h(\xi)$ when $\tilde{S}_h(\xi)$ is not necessarily normal, a fundamental theorem was given by H. O. Kreiss in 1962 [21].

If the largest-modulus eigenvalue of A is denoted by μ_0 , then the Friedrichs scheme is stable and hence is convergent under the condition on the mesh ratio $\lambda = \tau/h$ given by

$$\lambda \leq 1/|\mu_0|. \quad (43)$$

In particular, (43) implies that for the stable Friedrichs scheme

$$\text{propagation speed of the difference scheme} \geq \text{propagation speed of the original equation.} \quad (44)$$

Condition (44) is a necessary condition for general difference schemes approximating

hyperbolic equations to be stable, and is known as the **CFL condition** (Courant-Friedrichs-Lewy condition) [22]. For a scheme more accurate than the Friedrichs scheme we refer to the Lax-Wendroff scheme, which proceeds by way of the following amplification operator S_h :

$$\begin{aligned} S_h &= I + \tau A \delta_x^h + \frac{\tau^2}{2} A^2 D_x^h D_x^h \\ &= I + \frac{\lambda}{2} A (T_h + T_{-h}) + \frac{\lambda^2}{2} (T_h - 2I + T_{-h}). \end{aligned}$$

The Lax-Wendroff scheme is stable under (43).

There are many other difference schemes to approximate (39), most of which are applicable to higher-dimensional spaces. Some of these schemes can be conveniently employed to solve nonlinear hyperbolic equations, for instance, those arising in the gas dynamics of compressible fluids, for which the Friedrichs scheme and the Lax-Wendroff scheme were originally intended [23]. Concerning difference schemes with variable coefficients which approximate a regularly hyperbolic system with an x -dependent principal part, criteria for the stability of the scheme in terms of the symbol $\tilde{S}_h(x, \xi)$ of S_h have been obtained, making use of the theory of pseudodifferential operators, by P. D. Lax and L. Nirenberg (*Comm. Pure Appl. Math.*, 1966), M. Yamaguti and T. Nogi (*Publ. Res. Inst. Math. Sci.*, 1967), R. Vaillancourt (*Math. Comput.*, 1970), Z. Koshiba (*J. Math. Anal. Appl.*, 1981), and others.
